A B S T R A C T

Alzheimer’s disease (AD) is a neurodegenerative disorder involving impaired cholinergic neurotransmission and dysregulation of nicotinic acetylcholine receptors (nAChRs). Ly-6/neurotoxin (Lynx) proteins have been shown to modulate cognition and neural plasticity by binding to nAChR subtypes and modulating their function. Hence, changes in nAChR regulatory proteins such as Lynx proteins could underlie the dysregulation of nAChRs in AD. Using Western blotting, we detected bands corresponding to the Lynx proteins prostate stem cell antigen (PSCA) and Lypd6 in human cortex indicating that both proteins are present in the human brain. We further showed that PSCA forms stable complexes with the α4 nAChR subunit and decreases nicotine-induced extracellular-signal regulated kinase phosphorylation in PC12 cells. In addition, we analyzed protein levels of PSCA and Lypd6 in postmortem tissue of medial frontal gyrus from AD patients and found significantly increased PSCA levels (approximately 70%). In contrast, no changes in Lypd6 levels were detected. In concordance with our findings in AD patients, PSCA levels were increased in the frontal cortex of triple transgenic mice with an AD-like pathology harboring human transgenes that cause both age-dependent β-amyloidosis and tauopathy, whereas Tg2576 mice, which display β-amyloidosis only, had unchanged PSCA levels compared to wild-type animals. These findings identify PSCA as a nAChR-binding protein in the human brain that is affected in AD, suggesting that PSCA-nAChR interactions may be involved in the cognitive dysfunction observed in AD.

1. Introduction

Alzheimer’s disease (AD) is the most common form of dementia in the elderly individuals. Characteristics of AD consist of accumulation of β-amyloid (Aβ) plaques and neurofibrillary tangles of hyperphosphorylated tau proteins (Querfurth and LaFerla, 2010). Another neuropathologic feature of AD is the selective degeneration of cholinergic neurons in the basal forebrain, which is associated with the cognitive decline in AD (reviewed in Auld et al., 2002).

The most abundant nicotinic acetylcholine receptors (nAChRs) in the brain, α7 and α4β2, are involved in cognitive performance, such as attention and memory function, as well as synaptic plasticity (reviewed in Sarter et al., 2009; Thomsen et al., 2010). Accordingly, they have been widely investigated for their involvement in the pathology of AD. Genetic analyses have demonstrated associations between single-nucleotide polymorphisms in the α7 nAChR gene and AD (Carson et al., 2008b) as well as the delusional symptoms in AD (Carson et al., 2008a). Single-nucleotide polymorphisms in the genes of α4 (Dorszewska et al., 2005; Kawamata and Shimohama, 2002) and β2 nAChR subunits (Cook et al., 2004; Laumet et al., 2010) have also been shown to be associated with AD. Recent studies agree that α4β2 nAChR levels are decreased in AD. Thus, reduced [3H]-nicotine binding was observed postmortem in frontal cortex of AD patients (Marutle et al., 2013), and binding of the α4β2 nAChR radioligand [18F]-2FA-85380, by the use of PET, was decreased in several brain regions of AD patients and demonstrated significant correlations with both Aβ levels in the medial prefrontal cortex and cognitive performance of the AD patients (Okada et al., 2013). In contrast, there is currently no consensus on whether α7 nAChR levels in the brain are changed in AD, because binding
studies have reported either downregulation or no change (Court et al., 2001; Davies and Feusslin, 1981; Hellstrom-Lindahl et al., 1999; Marutle et al., 2013).

Aβ1–42 has been shown to bind both α7 and α4β2 nAChRs, the former with picomolar affinity, whereas its affinity for α4β2 was 5000 times lower (Wang et al., 2000). Furthermore, Aβ1–42 is able to modulate the function of both α7 and α4β2 nAChRs with dose-dependent effects (reviewed in Buckingham et al., 2009; Jurgensen and Ferreira, 2010).

In addition to Aβ1–42, several members of Ly-6/neurotoxins (Lynx) protein superfamily have been shown to modulate the function of nAChRs (reviewed in Miwa et al., 2011; Thomsen and Mikkelsen, 2012). Therefore, alterations in α7 and α4β2 nAChRs may be secondary to changes in Lynx protein levels.

The Lynx superfamily has structural similarities to snake venom toxins such as α-bungarotoxin and are characterized by a “three-fingered” loop motif (Ts et al., 1999). The Lynx proteins Lynx1 and Lynx2 have been shown to form stable complexes with and negatively regulate both α7 and α4β2 nAChRs (Ibanez-Tallon et al., 2002; Miwa et al., 2006; Tekinay et al., 2009). In addition, mice with genetic deletions of Lynx1 or Lynx2 displayed increased associative learning and elevated anxiety-like behavior, respectively (Miwa et al., 2006; Tekinay et al., 2009). Moreover, it was recently shown that Lynx1 through a nAChR-dependent action had a crucial role in the loss of synaptic plasticity observed in adult visual cortex (Morishita et al., 2010). Furthermore, transgenic overexpression of the Lynx protein Lypd6 in mice resulted in increased pre-pulse inhibition indicating possible involvement in attention (Darvas et al., 2009). Thus, Lynx proteins are suggested to be involved in cognitive function.

Prostate stem cell antigen (PSCA), another Lynx protein, was found to suppress nicotine-induced Ca2+ influx via activation of α7 nAChRs, when retrovirally expressed in dissociated avian ciliary ganglion neurons (Hruska et al., 2009). In contrast, nicotine-induced Ca2+ currents were enhanced in dissociated murine trigeminal ganglia neurons from transgenic mice overexpressing Lypd6, suggesting that Lypd6 is a positive modulator of nAChR function (Darvas et al., 2009).

Because nAChRs and Lynx proteins can bind directly to each other to affect cognitive function and synaptic plasticity, it is pertinent to examine the involvement of Lynx proteins in AD. The purpose of this study was to (1) investigate PSCA and Lypd6 in the human brain in relation to expression and complex formations with nAChR subtypes; (2) examine the ability of PSCA to modulate a nicotine-mediated response in PC12 cells; and (3) reveal whether the levels of the two Lynx proteins were changed in AD in both human AD patients and transgenic AD mouse models.

2. Methods

2.1. Human tissue

Temporal cortical tissue was obtained from anterior temporal lobectomies in two patients (1 female, aged 30 years and 1 male, aged 57 years) with medically intractable temporal lobe epilepsy with hippocampal onset. Written informed consent was obtained from both patients before surgery. The study was approved by the Medizinisch-Experimentelles Zentrum at Leipzig University. The day of experimentation, the mice were decapitated, frontal cortex and hippocampus dissected, and the tissue was immediately frozen on dry ice and stored at −80°C until use.

Twelve male Tg2576 mice expressing the hAPPswe mutations (Hsiao et al., 1996) and their WT littermates (n = 15) bred on an inbred 129S6 background were obtained from Taconic (Ry, Denmark). At the age of 9 months, in an unrelated set of experiments, the mice received bilateral intracerebroventricular phosphate-buffered saline (PBS) injections (Laursen et al., 2014) followed by electrophysiological testing. Mice were euthanized at the age of 15 months, and one hemisphere was dissected, snap frozen, and kept at −80°C until further analysis. Frontal cortex was later separated from the frozen sample and used for Western blot analyses as described in the following.

Experiments with 3 × Tg-AD were approved by the Animal Care and Use Committee of the University of Leipzig and local authorities (Regierungspräsidium Leipzig; T40/13) and conformed to the European Communities Council Directive (86/609/EEC). Experiments with Tg2576 mice were approved by the Danish National Committee for Ethics in Animal Experimentation.

2.3. Tissue fractionation

To fraction tissue into membrane and soluble fractions, human temporal cortical tissue from neurosurgery (150–170 mg, n = 2) was homogenized 2 × 30 seconds in Buffer1 (0.5 M NaCl, 50 mM Tris–HCl, 10 mM MgCl2, 2 mM ethylenediaminetetraacetic acid (EDTA), 10 μL/mL protease inhibitor cocktail [Sigma-Aldrich, Brandby, Denmark], pH 7.3) using a PT1200C polytron blender (Kinematica, Luzern, Switzerland) and centrifuged for 30 minutes

Key: F, female; M, male; PMD, postmortem delay.
at 126,000g at 20 °C—22 °C using an air-driven ultracentrifuge (Airfuge, Copenhagen, Denmark). The supernatant containing the soluble fraction was transferred to a new tube, and the pellet containing the membrane fraction was washed twice in Buffer1, resuspended by blending 2 × 30 seconds in Buffer2 (4 M urea, 50 mM Tris—HCl, 1% SDS, 10 µL/mL protease inhibitor cocktail, pH 7.3), and sonicated 3 × 5 seconds on ice.

2.4. PSCA affinity purification

Recombinant human GST-tagged PSCA produced in Escherichia coli (purchased from MyBioSource Inc, San Diego, CA) and dissolved to 0.7 mg/mL in PBS, pH 7.4 was coupled to PureProteome NHS Flexibind magnetic beads (Millipore, Billerica, MA) in a ratio of 1:1:25 (vol/vol). In brief, beads were washed once in ice-cold 1 mM HCl before addition of the PSCA solution. Subsequently, beads were incubated overnight at 4 °C in a rotator (15 rpm). Unbound PSCA was removed, and the beads were resuspended and washed four times in Quench buffer (100 mM Tris—HCl, 150 mM NaCl, pH 8.0) followed by incubation for 1 hour at room temperature. A batch of beads without PSCA in the PBS was processed in parallel as a negative control. The beads were incubated in 0.1% bovine serum albumin PBS in, pH 7.4, for 1 hour at 4 °C before use.

The tissue was lysed in 1 mL lysis buffer (50 mM Tris, 50 mM NaCl, 5 mM EDTA, 5 mM EGTA, 10 mg/mL protease inhibitor cocktail [Sigma-Aldrich], pH 7.5) using the PT1200C polycrylon blender for 20 minutes. The lysate was centrifuged for 30 minutes at 160,000g at 20 °C—22 °C using the air-driven ultracentrifuge and the supernatant discarded. The pellet was resuspended in 1 mL lysis buffer containing 2% Triton X-100 by blending for 20 seconds and incubated for 2 hours at 4 °C on a rotator (15 rpm). Thereafter, the sample was centrifuged as mentioned previously, and the resulting supernatant (input) was used for affinity purification. Total protein content was determined using the Pierce 660 nm Protein Assay (Thermo Scientific, Rockford, IL), and 100 µg protein was incubated with 50 µL magnetic beads in a total volume of 1500 µL lysis buffer for 18—22 hours at 4 °C in a rotator (15 rpm). A sample of the homogenate after affinity purification was taken (output). Subsequently, the beads were washed twice in 1 M NaCl, 8 mM Na₂HPO₄, 2 mM NaH₂PO₄, 0.5% Triton X-100, pH 7.5 and three times in an identical buffer, where 1 M NaCl was substituted with 0.1 M NaCl, and thereafter, the samples were immediately processed for Western blotting.

2.5. ERK phosphorylation and α2 nAChR expression in PC12 cells

PC12 cells were maintained in 75 cm² flasks coated with 5 µg/mL poly-L-lysine (Sigma-Aldrich), in Dulbecco modified Eagle medium (DMEM, Gibco Life Technologies, NY) supplemented with 10% heat-inactivated horse serum, 5% fetal bovine serum, 25 µL/mL penicillin, 25 µg/mL streptomycin, 1 mM sodium pyruvate, and 2 mM glutamine (complete culture medium) at 37 °C in a humidified incubator with 5% CO₂. Cells were subcultured every 3—4 days by detachment with 0.25% trypsin in EDTA solution (Gibco Life Technologies) and reseeded at 15% confluence.

For the extracellular-signal regulated kinase (ERK) phosphorylation assay, cells were seeded in 24-well plates at 12 × 10⁴ cells/cm², in low serum medium (1% heat-inactivated horse serum, 0.5% fetal bovine serum) 24 hours before the experiments, which started by incubating cells for 10 minutes with recombinant human PSCA protein (MyBiosource) in the concentrations (0.1, 1, and 10 µM) diluted in DMEM, followed by stimulation with 25 µM nicotine (Sigma-Aldrich) for 5 minutes. For the α2 nAChR expression assay, PC12 cells were seeded in 96-well plates at 12 × 10⁴ cells/cm² on the day of the experiment in complete culture medium. Subsequently, cells were stimulated for 24 hours with recombinant human PSCA protein (MyBiosource) in the concentrations (0.1, 1, and 10 µM) diluted in DMEM. Thereafter, cells were immediately lysed in 100 µL and 50 µL, respectively, ice-cold lysis buffer/well (100 mM NaCl, 25 mM EDTA, 10 mM Tris, 4 mM Na₂VO₄, 1 mM NaF, and 1% [vol/vol] Triton X-100, 1% [vol/vol] NP-40, 1 µL/mL protease inhibitor cocktail [Sigma-Aldrich], pH 7.4). To ensure complete lysis, lysates were then placed in −80 °C for 15 minutes, thawed, and sonicated for 5 seconds on ice. Lysates were stored at −80 °C until they were processed for Western blotting.

2.6. Small interfering RNA transfection and real-time quantitative reverse transcription polymerase chain reaction

FlexiTube small interfering RNA (siRNA) (Qiagen, Limburg, the Netherlands) against PSCA (TACAATCATCCTGTAAATAT) and a scrambled negative control were diluted in DMEM (Gibco Life Technologies) to a final concentration of 50 nM. The transfection reagent Lipofectamine 2000 (Life Technologies, Carlsbad, CA) was diluted in opti-MEM (Life Technologies) and incubated for 5 minutes at room temperature according to the manufacturer’s instructions. siRNAs were mixed with the transfection reagent and incubated further for 15 minutes at room temperature to allow the formation of transfection complexes. Subsequently, 100 µL of transfection complexes were added into each well of a 24-well plate, and PC12 cells were seeded at 24 × 10⁴ cells/cm² in complete culture medium without antibiotics. Cells were incubated at 37 °C in a humidified incubator with 5% CO₂. After 48 hours, the medium was removed, the plate was placed on ice, and RNA was immediately extracted using the RNeasy Mini Kit (Qiagen) according to the manufacturer’s instructions.

RNA samples were dissolved in RNase-free water, and RNA content was quantified using a Nanodrop ND-1000 Spectrophotometer (Nanodrop Technologies, Wilmington, DE). Samples were diluted with RNase-free water to equal RNA concentrations and reverse transcribed into single-stranded complementary DNA (cDNA) with the ImProm-II Reverse Transcription System (Promega, Madison, WI) according to the manufacturer’s directions using 0.5 g/reaction oligo(dT)₁₅ primers, 6 mM MgCl₂, and 20 units of RNase inhibitor. Real-time quantitative reverse transcription polymerase reactions (RT-qPCR) were performed in a total volume of 20 µL containing 1 µL sample cDNA, 1 × Brilliant II SYBR Green qPCR Master Mix (Stratagene, La Jolla, CA), and 15 pmol each of the forward and reverse primers (DNA Technology, Aarhus, Denmark). RT-qPCR was performed on a Light Cycler 480 Real-Time PCR System (Roche, Indianapolis, IN) with a 10-minute preincubation at 94 °C followed by 40 cycles of 30 seconds at 94 °C, 45 seconds at 60 °C, and 90 seconds at 72 °C. Primer pairs were validated by using serially diluted cDNA to establish a standard curve and by confirming the existence of a single product on a gel at the correct molecular weight. Quantification of messenger RNA (mRNA) expression was performed according to the comparative Cₗ method as described by (Schmittgen and Livak, 2008). For each sample, the amount of target mRNA was normalized to the amount of GAPDH.

The sequence of the designed primers were as follows: PSCA, forward 5’ GGCCCTACAGTCTGATGAC-3’, reverse 5’ TCACACCCACCTGCTGAT-3’; β₂ nAChR, forward 5’ ACGGGTCACCTGCGTCAT-3’, reverse 5’ CACACTCTGCTACATCCCT-3’, and GAPDH, forward 5’ CATCAA-GAAGTGTTGAAAGCA-3’, reverse 5’ CTTGTTGACTACAGGAAGA-3’.

2.7. Tissue preparation for Western blotting

Human postmortem cortical tissue was lysed in homogenization buffer (50 mM Tris, 100 mM NaCl, 25 mM EDTA, 1% [vol/vol] Triton-X, 1% [vol/vol] NP-40, 1 µL/mL protease inhibitor cocktail [Sigma-Aldrich], pH 7.4). Mouse cortical tissue was lysed in lysis buffer
(50 mM Tris–HCl, 4 M urea, 1% [wt/vol] SDS, 1 μL/mL protease inhibitor cocktail [Sigma-Aldrich], pH 7.4). All lysates were briefly sonicated 2 × 5 seconds and centrifuged at 1000g for 10 minutes at 4 °C. The resultant supernatant was used for detection of proteins using Western blotting as described in the following.

2.8. Western blotting

Total protein content was determined using the DC Protein Assay Kit (BioRad, Hercules, CA), and the samples were diluted in loading buffer (final concentration: 60 mM Tris, 10% [vol/vol] glycerol, 5% [vol/vol] mercaptoethanol, 2% [wt/vol] SDS, 0.025% [wt/vol] bromophenol blue, pH 6.8), incubated for 5 minutes at 95 °C, and submitted to gel electrophoresis using AnykD gels (BioRad). After blotting onto polyvinylidene difluoride membranes (BioRad), the membranes were washed in Tris-buffered saline with 0.1% Tween 20 (TBS-T), and blocked in TBS containing 5% (wt/vol) dry milk powder. Blots were incubated in primary antisera against PSCA (1:1,000, #ARP53451_P050, Aviva Systems Biology, San Diego, CA), β2 nAChR subunit (1:1,000, kindly provided by Dr Cecilia Gotti, previously characterized in Thomsen et al., 2014), GluR2 (1:200, #MABN71, Millipore), α4 nAChR subunit (1:100, sc-5591, Santa Cruz Biotechnology), α7 nAChR subunit (1:1000 #ab23832, Abcam, Cambridge, UK), or actin (1:10,000, #A5060, Sigma-Aldrich) overnight at 4 °C. Subsequently, blots were washed in TBS-T 3 × 10 minutes followed by 1 hour incubation at room temperature with horseradish peroxidase-conjugated secondary antibodies (1:2000, Dako, Glostrup, Denmark). After thorough washing in TBS-T, blots were visualized by enhanced chemiluminescence reagents (Western Lightning ECL Pro, Perkin Elmer, Waltham, MA) using a Chemidoc XRS system with Quantity One software (BioRad). Data were quantified by measuring mean optical densities of bands and subtracting an adjacent background measurement.

Validation of PSCA antibody (1:1,000, Novus Biologicals) was done with co-incubation with the PSCA peptide, which had been used as immunogen (1:100, NB100-91938PEP, Novus Biologicals). To determine the amount of endogenous PSCA in cortex, cortical samples from mouse and human cortex were loaded along with samples with known concentrations of the recombinant PSCA (0.5, 1, 2, 4, 8, and 16 ng). A standard curve was created based on the recombinant GST-tagged PSCA protein (total molecular weight 34.2 kDa) from human recombinant GST-tagged PSCA protein (total molecular weight 34.2 kDa) from 1 to 16 ng/well at the expected band size. Endogenous PSCA from mouse and human cortical tissue, α4 total protein/well detected at approximately 24 kDa, and the amount in the cortical samples was compared with the known concentrations of recombinant PSCA protein.

Fig. 1. Prostate stem cell antigen (PSCA) is soluble and co-purifies with the α4 nAChR subunit in human cortex. (A) The antiserum directed against PSCA recognizes the human recombinant GST-tagged PSCA protein (total molecular weight 34.2 kDa) from 1 to 16 ng/well at the expected band size. Endogenous PSCA from mouse and human cortical tissue, α4 total protein/well detected at approximately 24 kDa, and the amount in the cortical samples was compared with the known concentrations of recombinant PSCA protein. (B) Images of Western blot showing PSCA protein levels in cortical tissue from human (protein concentration 4, 8, and 12 μg/well) and mouse (8, 15, and 30 μg/well) in the absence (−peptide) and the presence of PSCA peptide (+peptide). (C) Representative images of Western blots showing PSCA and Lypd6 protein levels in soluble and membrane fractions of human temporal cortical tissue. The membrane receptor proteins β2 nAChR and GluR2 are used as control. (D) Magnetic beads covalently coupled with PSCA recombinant protein were incubated with cortical homogenates from human temporal cortex followed by detection of nAChR subunits by Western blot. Homogenates before (input) and after affinity purification (output) as well as the negative control (CTRL) were loaded.

2.9. Immunofluorescence labeling

Age-matched 3×Tg-AD and WT mice (n = 8) were perfused transcardially with phosphate-buffered 4% paraformaldehyde after being euthanized with CO2. Dissected brains were immersed in fixative overnight, dehydrated, and cut with a freezing microtome resulting in free-floating, 30-μm-thick coronal sections. Selected sections containing the frontal cortex or the hippocampal formation were used for phospho-tau and Aβ-immunolabeling according to an earlier protocol with minor modifications (Hartig et al., 2014). Tissues were incubated with a mixture of biotinylated mouse-anti-Aβ(1-24) (4G8; Covance, Emeryville, CA; 1:400 in TBS with 5% normal donkey serum) and rabbit-anti-phospho-tau205 (Invitrogen, Karlsruhe, Germany; 1:300) overnight. Subsequently, the sections were rinsed with TBS and incubated for 1 hour in a mixture of carboxyamine 2 (Cy2)-conjugated streptavidin and Cy3-tagged donkey anti-rabbit IgG (both from Dianova, Hamburg, Germany; 20 μg/mL TBS containing 2% bovine serum albumin). After washing with TBS, the sections were treated with Sudan Black B for 10 minutes (Schnell et al., 1999) and mounted onto glass slides. For data illustration, images were taken from selected sections using a 510 Meta confocal laser-scanning microscope (Zeiss, Jena, Germany) and processed with CorelDraw and/or Photo-Paint version 12.0 (Corel Corp, Ottawa, Canada).

2.10. Statistical analyses

Data from PC12 cells were analyzed using one-way analysis of variance (ANOVA) with Dunnett multiple comparisons test. Correlation of age, postmortem delay, and pH with protein levels in human subjects was done using Pearson correlation analysis. Two-way ANOVA was applied to analyze effects of genotype and age in 3×Tg-AD mice. Unpaired multiple t tests using the Holm-Sidak method was used to compare groups. The statistical calculations were performed using GraphPad Prism version 6 for Windows (GraphPad Software, San Diego, CA). Data are presented as mean ±
standard error of the mean, and \( p < 0.05 \) was considered as statistically significant.

3. Results

3.1. PSCA is a soluble protein that binds to α4 nAChR subunits in the human cortex

The PSCA antiserum recognized recombinant human PSCA protein in the concentration range of 1–16 ng/well at molecular weight band of approximately 34 kDa (Fig. 1A). Recombinant PSCA protein consisted of 75 amino acids (immunogen sequence positions 21–95) with a calculated molecular weight of 8.2 kDa. However, this protein was GST-tagged (approximately 26 kDa) resulting in a total molecular weight of approximately 34 kDa, which correlated with the molecular weight of the identified protein (Fig. 1A). A band at a molecular weight of approximately 24 kDa was detected by Western blotting in extracts from both human frontal cortex (Fig. 1A), human temporal cortex (Fig. 1B), and mouse frontal cortex (Fig. 1A and B). To estimate protein levels of PSCA in cortical tissue, the intensity of PSCA staining in cortical samples was compared with that of recombinant PSCA with known concentrations (Fig. 1A). Based on the standard curve, cortical tissue was estimated to contain 0.3 and 0.5 ng/μg total protein for mouse and human cortex, respectively. Co-incubation of the diluted PSCA antiserum with the immunogen peptide prevented detection of bands in both human and mouse cortical extracts (Fig. 1B).

Human temporal cortical tissue was fractionated into soluble and membrane fractions by ultracentrifugation, and the resulting fractions were subjected to Western blotting (Fig. 1C). PSCA was detectable only in the soluble fraction. On the contrary, Lypd6 was detected only in the membrane fraction. To validate the fractionation method, we show that the two receptor units, β2 nAChR and GluR2, were only present in the membrane fraction (Fig. 1C).

Affinity purification from human temporal cortical homogenates using magnetic beads coupled to recombinant human PSCA demonstrated that PSCA was able to isolate the α4 nAChR subunit (Fig. 1D). Affinity purification using uncoupled beads yielded no isolation of α4 protein. By contrast, PSCA did not isolate the α7 nAChR subunit.

3.2. PSCA regulates nicotine-induced ERK phosphorylation in PC12 cells

Nicotine induces phosphorylation of the MAP kinase ERK in PC12 cells (Fig. 2A). Recombinant human PSCA at 10 μM significantly inhibited nicotine-induced ERK phosphorylation by approximately 30% in PC12 cells (\( p < 0.01 \)), whereas 0.1 and 1 μM had no significant effects. PSCA alone did not affect basal levels of ERK phosphorylation.

Stimulation of PC12 cells with PSCA (0.1, 1, and 10 μM) for 24 hours did not alter β2 protein levels (Fig. 2C). In addition, β2 mRNA levels in PC12 cells were unchanged, when silencing PSCA levels using PSCA siRNA (Fig. 2E). The expression of PSCA was reduced to approximately 40% by PSCA siRNA, when compared with the expression in the presence of the negative control siRNA.

3.3. PSCA levels are increased in frontal cortex of AD patients

PSCA, Lypd6, and β2 protein levels were determined in human postmortem cortical tissue from medial frontal gyrus using Western blotting (Fig. 3). The levels of PSCA were increased by approximately 70% in AD postmortem tissue compared with non-demented (non-AD) control subjects (1.71 ± 0.16, \( p = 0.0025 \)), whereas Lypd6 levels were unchanged (0.99 ± 0.12, \( p = 0.97 \)). Levels of the β2 nAChR subunit were significantly decreased in AD patients (0.66 ± 0.06, \( p = 0.014 \)).

Although AD subjects were noted to be slightly younger and have slightly shorter postmortem delay than the non-AD control subjects (see Table 1), we found no correlation between any of these parameters or pH with protein levels of PSCA, Lypd6, and β2 nAChR within the non-AD or AD groups.
3.4. PSCA levels are increased in frontal cortex of 3 × Tg-AD mice

Protein levels of PSCA, Lypd6, and the β2 nAChR subunit were determined in frontal cortex and hippocampus from 6 to 19- to 21-month-old 3 × Tg-AD mice and age-matched WT controls using Western blotting (Fig. 4). In frontal cortex using two-way ANOVA with age and genotype as independent variables, there was no interaction of the variables, but a significant main effect of genotype on PSCA and β2 nAChR levels in 3 × Tg-AD mice in the two age groups (p < 0.01 and p < 0.05, respectively) compared with age-matched WT mice (Fig. 4A), whereas there was no significant main effect of age. Subsequent unpaired t tests revealed that the effect of genotype was driven primarily by the 6-month group, where 3 × Tg-AD mice had significantly enhanced PSCA (1.46 ± 0.17, p = 0.038) and significant lower β2 nAChR levels (0.79 ± 0.04, p < 0.01) compared with age-matched WT animals. PSCA and β2 nAChR levels in 19- to 21-month-old 3 × Tg-AD mice were not significantly altered in unpaired t tests (p = 0.10 and p = 0.23, respectively). In the hippocampus (Fig. 4A), there were no significant main effects on PSCA and β2 nAChR levels of genotype (p = 0.05 and p = 0.06, respectively) or age (p = 0.19 and p = 0.35, respectively) in a two-way ANOVA. A two-way ANOVA did not reveal any main effect of genotype or age in Lypd6 levels in frontal cortex (p = 0.98 and p = 0.80, respectively) or hippocampus (p = 0.42 and p = 0.94, respectively).

Immunofluorescence labeling was applied to sections of frontal cortex and hippocampus in 21-month-old 3 × Tg-AD mice (Fig. 4C). Frontal cortex displayed extracellular amyloid plaques as well as intracellular deposits intermingled with phospho-tau immunoactivity. In hippocampus, tau hyperphosphorylation was present, and β-amyloidosis was more pronounced than in frontal cortex (Fig. 4C). In 6-month-old 3 × Tg-AD mice, weak intracellular Aβ staining was displayed in both frontal cortex and hippocampus. The staining of tissues comprising frontal cortex and the hippocampus in age-matched WT mice revealed neither Aβ-immunoreactive senile plaques nor hyperphosphorylated tau (see Supplementary Fig. 1).

3.5. PSCA levels are unchanged in frontal cortex of Tg2576 mice

In frontal cortex of Tg2576 mice, there were no significant changes in the levels of PSCA, Lypd6, and β2 nAChR subunit (Fig. 5) compared with WT animals in unpaired t tests.

4. Discussion

Here, we show that the Lynx proteins PSCA and Lypd6 are present in the human brain and that PSCA forms stable complexes with the α4 nAChR subunit in the human temporal cortex and is able to decrease nicotine-induced ERK phosphorylation in PC12 cells. We further demonstrate that PSCA is increased in the frontal cortex of AD patients as well as in 3 × Tg-AD mice. Because 3 × Tg-AD display both age-dependent β-amyloidosis and tauopathy, this finding suggests that increased levels of PSCA are linked to the pathophysiology of AD.

PSCA was first identified as a protein that was upregulated in prostate cancer (Reiter et al., 1998). PSCA mRNA has previously been demonstrated in the central nervous system of adult mouse and chicken embryos (Hruska et al., 2009), and Lypd6 mRNA has been found in human and mouse brain tissue (Darvas et al., 2010). We demonstrate that PSCA and Lypd6 proteins are present in the human cortex. Because these Lynx proteins have been associated with regulation of nAChR function in dissociated neurons from chicken and mouse (Darvas et al., 2009; Hruska et al., 2009), it is pertinent to study their function in the healthy and diseased human brain.

Lynx proteins can exist as either glycosylphosphatidylinositol (GPI)-anchored membrane proteins or soluble proteins (Adermann et al., 1999; Bamezai, 2004). PSCA mRNA contains a GPI anchor signaling site (Hruska et al., 2009; Reiter et al., 1998), and PSCA protein is both secreted and cell-associated in PSCA-transfected 293T cells (Reiter et al., 1998). We detected native PSCA in the human brain exclusively as a soluble protein. Lypd6 was found to be membrane-bound in the human cortex, which is in line with previous data on rat cortical tissue (Thomsen et al., 2013). Some GPI-anchored proteins have been shown to have both membrane-bound and secreted forms, for example, CD59, another member of the Lynx superfamily (Fritz and Lowe, 1996; Meri et al., 1996). Soluble Lynx can diffuse to sites not available to the membrane-bound GPI-anchored proteins. This may have an impact on how Lynx proteins exert their function, for example, it was reported that transgenic mice expressing secreted or full-length Lynx1, respectively, show different effects in terms of motor learning (Miwa and Walz, 2012).

We demonstrate that PSCA and the α4 nAChR subunit form stable complexes in human cortex using affinity purification with recombinant PSCA. We have recently shown that Lypd6 binds to multiple nAChR subtypes in the human cortex (Thomsen et al., 2013), and Lynx1 and Lynx2 have been shown to co-immunoprecipitate with α7 and α4β2 nAChR subunits in...
Prostate stem cell antigen (PSCA) levels are increased in frontal cortex of 3×Tg-AD mice. (A) Frontal cortex and hippocampus were dissected from triple transgenic (3×Tg-AD) mice and age-matched wild-type (WT) animals, homogenized, and protein analysis was performed using Western blotting. Data are normalized to actin levels, and the 6-month-old WT group is set to 1 (n = 7–8 per group). *p < 0.05, **p < 0.01 indicates significant main effect of genotype in two-way analysis of variance. ‘p < 0.05, “p < 0.01 indicates statistical difference between 6-month-old 3×Tg-AD and age-matched WT mice in unpaired t tests. (B) Representative Western blot images of protein levels in frontal cortex and hippocampus. (C) Immunofluorescence labeling and confocal laser-scanning microscopy of neuropathologic alterations in the frontal cortex (I, III, V) and the hippocampal formation (II, IV, VI) from a 21-month-old 3×Tg-AD mouse. Biotinylated 4G8 visualized by green fluorescent Cy2-streptavidin reveals both extracellular plaques and intracellular deposits in the frontal cortex (I), whereas indirect immunolabeling with rabbit-anti-phospho-tau (Cy3, red) shows hyperphosphorylation in the same neocortical area (III). In the hippocampus, several 4G8-immunopositive plaques are detectable (II), and abnormally phosphorylated tau is found in numerous cells including pyramidal neurons (IV). Merged pictures (V, VI) indicate the allocation of the neuropathologic alterations. Scale bar = 75 μm. Fig. 4.

ERK phosphorylation in PC12 cells through α3β4 (Nakayama et al., 2006) and to some extent α7 nAChRs (El Kouhen et al., 2009; Gubbins et al., 2010). We show that 10 μM PSCA inhibits nicotine-induced ERK phosphorylation in PC12 cells with no effect on basal levels of ERK phosphorylation indicating that the inhibitory effect is unique to nAChR signaling. The concentration of PSCA corresponds to studies with Lynx1, which showed that 10 μM Lynx1 was able to inhibit Ach-induced currents in Xenopus oocytes expressing human α7, α4β2, and α3β2, whereas 1 μM Lynx1 was not (Lyukmanova et al., 2011). These data suggest that PSCA could bind to α7 nAChRs, although we were not able to detect it and possibly also to α3β4 nAChRs. Thus, PSCA may function as a modulator of nAChR function in the brain. That PSCA affects a signaling pathway known to be important for neural plasticity and memory, makes it an interesting target for future studies.

With the demonstration that PSCA and Lypd6 bind to and modulate nAChRs, it is pertinent to investigate the function of PSCA and Lypd6 in diseases, where nAChRs are dysregulated, such as AD. nAChRs are important for normal cognitive function, and some studies suggest a correlation between nAChR levels and cognitive deficits in AD (Nordberg et al., 1995; Okada et al., 2013; Perry et al., 2000). Recent studies suggest that Lynx1, Lynx2, and Lypd6 are involved in cognitive processes in rodents (Darvas et al., 2009; Tekinay et al., 2009). These studies suggest that there may be an interesting target for future studies.

To investigate the potential effect of PSCA on nAChR function, we determined the effect of PSCA on nicotine-induced phosphorylation of the MAP kinase ERK. Activation of the intracellular MAPK/ERK signaling pathway by phosphorylation plays a crucial role in the formation of long-term potentiation and memory in hippocampus (Adams and Sweatt, 2002). Nicotine has been suggested to induce ERK phosphorylation in PC12 cells through α3β4 (Nakayama et al., 2006) and to some extent α7 nAChRs (El Kouhen et al., 2009; Gubbins et al., 2010). We show that 10 μM PSCA inhibits nicotine-induced ERK phosphorylation in PC12 cells with no effect on basal levels of ERK phosphorylation indicating that the inhibitory effect is unique to nAChR signaling. The concentration of PSCA corresponds to studies with Lynx1, which showed that 10 μM Lynx1 was able to inhibit Ach-induced currents in Xenopus oocytes expressing human α7, α4β2, and α3β2, whereas 1 μM Lynx1 was not (Lyukmanova et al., 2011). These data suggest that PSCA could bind to α7 nAChRs, although we were not able to detect it and possibly also to α3β4 nAChRs. Thus, PSCA may function as a modulator of nAChR function in the brain. That PSCA affects a signaling pathway known to be important for neural plasticity and memory, makes it an interesting target for future studies.

With the demonstration that PSCA and Lypd6 bind to and modulate nAChRs, it is pertinent to investigate the function of PSCA and Lypd6 in diseases, where nAChRs are dysregulated, such as AD. nAChRs are important for normal cognitive function, and some studies suggest a correlation between nAChR levels and cognitive deficits in AD (Nordberg et al., 1995; Okada et al., 2013; Perry et al., 2000). Recent studies suggest that Lynx1, Lynx2, and Lypd6 are involved in cognitive processes in rodents (Darvas et al., 2009; Tekinay et al., 2009). These studies suggest that there may be an interesting target for future studies.

heterologous expression systems (Ibanez-Tallon et al., 2002; Tekinay et al., 2009). These studies suggest that there may be an entire subfamily of Lynx proteins that bind to nAChRs in the brain.

It has previously been suggested that PSCA may be a negative modulator of α7 nAChRs in chicken ciliary ganglion neurons (Hruska et al., 2009). We did not detect co-purification of the α7 nAChR subunit using PSCA affinity purification on human cortical extracts. Possibly, the binding between PSCA and the α7 nAChR subunit is not strong enough to be detected in our assay. Alternatively, the binding of PSCA to nAChR subunits differs between species, as it has been shown for Lynx1. Human Lynx1 competes with binding of the α7 nAChR antagonist α-bungarotoxin to acetylcholine-binding proteins and Torpedo nAChRs with an IC50 of approximately 10 μM, suggesting that it binds to the orthosteric site, whereas it does not compete with α-bungarotoxin binding to human α7 nAChRs or with [3H]-epibatidine binding to human α4β2 nAChRs (Lyukmanova et al., 2011).

To investigate the potential effect of PSCA on nAChR function, we determined the effect of PSCA on nicotine-induced phosphorylation of the MAP kinase ERK. Activation of the intracellular MAPK/ERK signaling pathway by phosphorylation plays a crucial role in the formation of long-term potentiation and memory in hippocampus (Adams and Sweatt, 2002). Nicotine has been suggested to induce
plex (Davies et al., 1989), has been demonstrated to be a member of the Lynx superfamily CD59, which is involved in the regulation of nAChR neuromodulator (Darvas et al., 2009; Thomsen et al., 2002), the dysfunction of the receptor may have negative impact on attention and executive function as has been described previously (Okada et al., 2013; Sarter et al., 2009). Lypd6 also binds to the nAChR subunit and inhibits nAChR signaling, increased PSCA levels may decrease nAChR function in patients with AD. If PSCA is able to inhibit the function of nAChRs similar to Lynx1 (Ibanez-Tallon et al., 2002), the dysfunction of the receptor may have negative impact on the cognitive performance of the AD patients especially on attention and executive function as has been described previously (Okada et al., 2013; Sarter et al., 2009). Lypd6 also binds to nAChRs in human cortex (Thomsen et al., 2013) and is suggested as a nAChR neuromodulator (Darvas et al., 2009; Thomsen et al., 2013), but we found no change in Lypd6 levels in AD. Another member of the Lynx superfamily CD59, which is involved in the innate immune system as inhibitor of the membrane attack complex (Davies et al., 1989), has been demonstrated to be down-regulated in AD (Yang et al., 2000). Alterations of both PSCA and CD59 in AD suggest that some Lynx proteins may be involved in the disease.

Therefore, we asked whether altered protein levels of PSCA are related to AD pathophysiology. We found increased PSCA protein levels in frontal cortex of 3×Tg-AD animals that overexpress Aβ and hyperphosphorylated tau, the hallmarks of AD pathology. This indicates that the combination of increased Aβ and hyperphosphorylated tau are sufficient to increase in PSCA protein and suggest that the increase in PSCA levels found in AD patients is linked to the pathophysiology of AD. PSCA levels were not altered in transgenic Tg2576 mice that overexpress the Aβ precursor APP and display increased Aβ levels (Hsiao et al., 1996). This suggests that increased Aβ levels are not sufficient to increase PSCA levels. However, it should be noted that APP transgene animal models, such as the Tg2576 mice, show a slower accumulation of Aβ plaques than the 3×Tg-AD mouse model (reviewed by Lee and Han, 2013), so the lack of effect in the model may reflect lower Aβ load. Furthermore, the progression and dynamics of AD pathology in 3×Tg-AD mice are rather similar to the pathogenesis in AD patients (Bilkei-Gorzo, 2014), where Aβ deposition begins first in cortical regions and later in hippocampus, whereas tau pathology initiates in limbic regions and then progresses to cortical regions (Oddo et al., 2003). Here, we demonstrate by immunofluorescence labeling of frontal cortex and hippocampus from 3×Tg-AD mice a pronounced AD-like pathology in 21-month-old animals, whereas 6-month-old animals are displaying intracellular Aβ immunoreactivity but are devoid of amyloid plaques or apparent tau pathology suggesting that the changes in PSCA are not driven by tau pathology alone. Intracellular immunoreactivity in the young animals could indicate cross-reactivity of the applied antibody 4G8 for APP as previously reported (Härtig et al., 2014; Winton et al., 2011). Because we show the strongest increase of PSCA levels in 6-month-old 3×Tg-AD mice, our data indicate that the regulation of PSCA levels occurs before Aβ plaque and neurofibribrillary tangle formation, although this does not preclude an involvement of soluble Aβ forms in the regulation of PSCA levels. Because both Aβ and PSCA can bind to nAChRs, they may share the same nAChR-binding site. However, it has been proposed that binding of Aβ to different nAChR subtypes may involve different binding sites (Nery et al., 2013). Our data suggest that increase in PSCA may be a precursor to stages of plaque overload in the 3×Tg-AD mice, suggesting that the regulation of PSCA is an early event in the progression of AD pathology in this animal model.

Because PSCA binds to α4-containing nAChRs, the altered expression of nAChRs in AD could be a consequence of changes in PSCA or vice versa. We demonstrate that β2 nAChR levels are decreased in frontal cortex of AD patients and 3×Tg-AD mice, whereas they are not changed in Tg2576 animals and in the hippocampus of 3×Tg-AD mice, where we do not observe increased PSCA levels. However, when we investigated PSCA in PC12 cells, we did not find alterations of β2 expression at both mRNA and protein levels in the absence or presence of PSCA, respectively. It should be noted that these findings do not exclude that PSCA is able to change β2 expression in native tissue and/or under pathologic conditions. The finding that PSCA and β2 nAChR levels are not increased in hippocampus of 3×Tg-AD mice could be because of different origin of the cholinergic input to frontal cortex and hippocampus, respectively. Pathologic changes in the nuclei of the basal forebrain may therefore influence the expression of PSCA and β2 nAChRs more prominently in the frontal cortex. Regulation of frontal cortical α4β2 nAChR expression in early-stage AD has previously been demonstrated in humans, for example, a significant reduction in α4β2 binding in vivo in frontal cortex of patients with mild cognitive impairment (Kendziorska et al., 2011) and early-stage AD, which correlated with high [11C]-Pib uptake as a measure of amyloid deposits (Okada et al., 2013). In addition, [14C]-nicotine autoradiography in postmortem frontal cortical tissue showed a significantly reduced binding in AD patients (Marufite et al., 2013). Given our data that PSCA binds to the α4 nAChR subunit, and the fact that α4 and β2 nAChR subunits form heteromers, increased PSCA expression may influence α4β2 nAChR levels in AD.

![Fig. 5. No changes in prostate stem cell antigen (PSCA) levels in frontal cortex of Tg2576 mice over-expressing β-amyloid. (A) Frontal cortical extracts dissected from 15-month-old male Tg2576 mice and age-matched wild-type (WT) controls were homogenized and followed by Western blotting for protein analysis. (B) Representative images of Western blots. Data are normalized to actin levels, and the WT group is set to 1 (n = 12–14 per group).](image-url)
In summary, our findings have identified PSCA as a nAChR-binding protein in the human brain. PSCA inhibits nAChR signaling in vitro and is dysregulated in the frontal cortex of AD patients as well as animal models with AD pathology. Therefore, PSCA-nAChR interactions may affect cognitive function particularly in the context of AD pathology.
