ABSTRACT

The major human pathogen *Mycobacterium tuberculosis* can survive in the host organism for decades without causing symptoms. A large cohort of Toxin–Antitoxin (TA) modules contribute to this persistence. Of these, 48 TA modules belong to the vapBC (virulence associated protein) gene family. VapC toxins are PIN domain endonucleases that, in enterobacteria, inhibit translation by site-specific cleavage of initiator tRNA. In contrast, VapC20 of *M. tuberculosis* inhibits translation by site-specific cleavage of the universally conserved Sarcin-Ricin loop (SRL) in 23S rRNA. Here we identify the cellular targets of 12 VapCs from *M. tuberculosis* by applying UV-crosslinking and deep sequencing. Remarkably, these VapCs are all endoribonucleases that cleave RNAs essential for decoding at the ribosomal A-site. Eleven VapCs cleave specific tRNAs while one exhibits SRL cleavage activity. These findings suggest that multiple vapBC modules contribute to the survival of *M. tuberculosis* in its human host by reducing the level of translation.

INTRODUCTION

The major human pathogen *Mycobacterium tuberculosis*, the causative agent of tuberculosis (TB), currently infects more than 8 million and kills > 1 million people per year (1). The prevalence of multi-drug resistant TB is increasing and is a cause for significant concern (2). *M. tuberculosis* can persist latently without symptoms for many years in human carriers (3). The molecular mechanisms underlying latency and slowed bacterial growth are still poorly understood but may involve multiple regulatory pathways. One of these depends on the stringent response and Toxin–Antitoxin (TA) modules (4).

All bacteria produce slow growing ‘persistence cells’ that are tolerant to a broad spectrum of antibiotics (5,6). Recent research on *Escherichia coli* and *Salmonella* shows that persistence is controlled by the stringent response and TA modules. Such TA modules are almost ubiquitous in bacteria and are often present in perplexingly high numbers (7). *Mycobacterium tuberculosis* has at least 88 type II TAs (8,9), raising important questions concerning their biological function(s).

Type II TA modules encode two genes in an operon, a protein ‘toxin’ that inhibits cell growth and a protein ‘antitoxin’ that counteracts the inhibitory effect of the toxin by direct protein contact (10). The antitoxins are usually metabolically unstable while the toxins are stable. Thus, regulated proteolysis of a given antitoxin determines the activity of the cognate toxin. Evidence from *E. coli* K-12 and *Salmonella* indicates that TA modules are effector genes that induce persistence when activated and step-wise deletion of 10 type II TAs progressively reduced persistence (11). Correspondingly, inactivation of Lon, the protease that degrades all known type II antitoxins of *E. coli* K-12, strongly reduced persistence. Remarkably, the TAs of *E. coli* are induced stochastically by a mechanism that depends on (ppp)Gpp, polyphosphate and Lon. In a population of rapidly growing cells, approximately 10\(^{-3}\) have a high level of (ppp)Gpp that leads to accumulation of polyphosphate, which activates Lon to degrade antitoxins. Toxin activation then leads to growth arrest, multidrug tolerance, and persistence (12). Independent support for this model has come from several comprehensive studies of *Salmonella enterica* serovar Typhimurium. *S. Typhimurium* has up to 20 type II TAs and deletions of single TA loci showed reduced survival of *S. Typhimurium* within fibroblasts (13). Furthermore, deletion of single TA genes reduced persister cell formation and survival when the bacterium was grown inside macrophages (14). Consistently, multiple type II TAs have been found to be activated in *S. Typhimurium* when residing...
inside macrophages (15). Studies with M. tuberculosis also support a role for TAs in persistence and virulence (8,16,17).

*Mycobacterium tuberculosis* has a highly expanded repertoire of TA modules, with 48 representatives of the *vapBC* family (7,8) (Figure 1A). VapC toxins are PIN (pilT N-terminal) endoribonucleases containing three or four conserved acidic residues that coordinate Mg$^{2+}$ ion(s) in the active site (18). In Eukaryotes, PIN domains have been identified in multidomain endonucleases involved in RNA metabolism, RNA quality control and rRNA maturation (19). In Prokaryotes, however, most PIN domain proteins belong to the highly abundant VapC toxin family that are present in staggering numbers in certain prokaryotic genomes, including *M. tuberculosis* (7–9).

The molecular targets of most prokaryotic VapCs are unknown; however, the VapCs of *S. Typhimurium*, *Shigella flexneri* and *Leptospira interrogans* cleave initiator tRNA site-specifically in the anticodon loop, thereby inhibiting translation (20,21). In contrast, VapC20 of *M. tuberculosis* inhibits translation via cleavage of the conserved Sarcin–Ricin loop (22).

Here, we applied UV-induced RNA-protein crosslinking and analysis of cDNA by high throughput sequencing (CRAC) to identify transcriptome-wide targets of VapC paralogues in *M. tuberculosis* using *M. smegmatis* as a surrogate host organism. First, we identified the cellular targets of six different VapCs and showed that they all cleave tRNAs site-specifically within the anticodon loop. We then used phylogenetic analysis to identify the cellular targets of an additional six VapCs. Several of these VapCs were previously shown to have non-specific RNase activity in vitro (23–25). Strikingly, we show that all 12 VapCs catalyse site-specific cleavage of RNAs essential for protein synthesis.

**MATERIALS AND METHODS**

Strains, plasmids and growth conditions

*Mycobacterium smegmatis* strain MC$^{2}$155 was routinely grown in LB medium (Difco) containing 0.1% Tween-80 (LBT) at 37°C. For UV-crosslinking experiments strain procedure. (A) Chromosomal location of 48 *vapBC* modules (7,8). Genes shown in blue are analysed here, gene shown in red was analysed previously (22). (B) Growth-inhibition tests of selected *vapCs* of *M. tuberculosis* in *M. smegmatis* strain MC$^{2}$155 containing plasmid pMEND carrying a tetracycline inducible promoter and encoding C-terminally His-TEV-FLAG tagged (HTF) vapC genes. Strain MC$^{2}$155 carrying vapC4 (Rv0595c), vapC11 (Rv1561), vapC15 (Rv2010), vapC25 (Rv0277c), vapC26 (Rv0582), vapC28 (Rv0609), vapC29 (Rv0617), vapC30 (Rv0624), vapC32 (Rv1114), vapC33 (Rv1242), vapC37 (Rv2103c) or vapC39 (Rv2530c) were grown overnight in LBT at 37°C. The optical density (OD$_{600}$) was then adjusted to 0.5, and the bacterial cultures serially diluted (10-fold) and spotted (3 µl) on nutrient agar plates without or with inducer (20 ng/ml tetracycline). The plates were incubated 3 days at 37°C. (C) Outline of Crosslinking and Analysis of cDNA protocol (CRAC). (1) The HTF tagged VapC protein is UV cross-linked (UV-C) with target RNAs in vivo, the RNA–protein complexes are purified and the RNA trimmed by a cocktail of RNase A, T1 and barcoded linkers are ligated to the RNA. (2) cDNA is synthesized by reverse transcription using 3′-end specific primer and the library generated by PCR. (3) Finally, the DNA library is purified and deep sequenced using the Illumina platform. The sequencing output is aligned and analysed using the pyCRAC software package.
MC²155 was grown in M9 medium (Difco) containing 0.1% Tween-80 (M9T) with 0.1% Casein hydrolysate, 1 µg/ml thiamine and 0.2% glucose as carbon source at 37°C. When appropriate, 50 µg/ml kanamycin was added the medium to maintain the plasmid. Furthermore, when stated 20 ng/ml tetracycline was added to liquid or solid medium to induce transcription from tetracycline inducible promoters.

Plasmids
Construction of plasmids is described in Supplementary Information; Supplementary Table S1 contains a list of oligonucleotides used to construct plasmids and to detect RNAs in northern analysis.

Crosslinking and analysis of cDNA
Cultures (2 l) of *M. smegmatis* MC²155 containing plasmids pMEND::HTF, pMEND::vapC4::HTF, pMEND::vapC11::HTF, pMEND::vapC28::HTF, pMEND::vapC29::HTF, pMEND::vapC30::HTF, pMEND::vapC37::HTF, were grown exponentially in M9T at 37°C under constant aeration. At OD₆₀₀ = 0.3–0.4 cultures were induced by addition of 20 ng/ml tetracycline. After 20 min of incubation cultures were irradiated with 1800 mJ of UV-C for 100 seconds (Van Remmen UV Techniek). The cells were subsequently harvested by centrifugation, washed in ice-cold phosphate buffered saline (PBS) containing 0.1% Tween-80 and snap frozen in liquid nitrogen. The pellets were stored at −80°C. The HTF tagged proteins were then purified, linkers ligated to crosslinked RNA, cDNA synthesized and DNA libraries generated as described in (26). The DNA libraries were then sequenced on the illumina MiSeq platform and the sequencing output analysed using the pyCRAC tool package (27).

Northern blotting analysis of tRNA and rRNA after VapC induction
*M. smegmatis* MC²155 containing plasmid pMEND-HTF with VapC of interest were grown exponentially in LBT containing kanamycin (50 µg/ml) at 37°C. At an OD₆₀₀ of 0.3–0.4, vapC transcription was induced by the addition of tetracycline (20 ng/ml). A sample was collected before and after 120 min of incubation with inducer. Total RNA was purified using the FastRNA Blue Kit (MPbiomedicals) according to manufactures instructions. The cell samples were lysed by homogenization using the MagNA lyzer (Roche) twice at 6500 rpm for 40 s, separated by a 1 min rest on ice. After precipitation the RNA was dissolved in nuclease free water. Total RNA (2.5 µg) was denatured in Formamide loading buffer and separated on a 4.5% (rRNA) or 8% (tRNA) 8 M urea polyacrylamide gel in 1× TBE (100 mM Tris–borate and 2 mM ethylenediaminetetraacetic acid, EDTA). The RNA was then transferred to a Zeta-Probe membrane (Bio-Rad) by semi-dry electrophoretic transfer and the membrane pre-hybridized with SESI buffer (0.25 M NaPO₄ pH 7.2, 1 mM EDTA and 7% SDS) at 42°C for at least 30 min. Probe oligonucleotides (20 pmol) (see Supplementary Table S1) were labelled using 30µCi γ³²P-ATP and T4 Polynucleotide kinase (Fermentas) according to manufactures procedures and added to the membrane (due to the high primary sequence similarity between *M. smegmatis* and *M. tuberculosis* tRNAs, *M. smegmatis* tRNA probes could be used in most cases except for tRNA₂₅ Ser(−GGA) and tRNA₂₈ Ser(−GGA)). The tube was then incubated overnight at 29°C in a hybridization oven. After hybridization the membrane was washed 2–3 times in SES3 buffer (0.25 M NaPO₄ pH 7.2, 1 mM EDTA and 5% SDS) at room temperature. The bands were visualized by phosphorimaging. The membrane could be stripped with repeated washes of 0.1% SDS at 85°C and subsequently re-probed.

Purification of VapC4-HTF, VapC11-HTF, VapC28-HTF and VapC37-HTF
VapC toxins were purified from *Mycobacterium smegmatis* using histidine affinity chromatography as we described previously (22). *Mycobacterium smegmatis* MC²155 containing plasmids pMEND::vapC4::HTF, pMEND::vapC11::HTF, pMEND::vapC28::HTF and pMEND::vapC37::HTF were grown exponentially in 1-l LBT at 37°C with shaking. At OD₆₀₀ = 0.4, the culture was induced with tetracycline (20 ng/ml) for 1 h before cells were pelleted by centrifugation. The cells were then washed in ice-cold PBS containing 0.1% Tween-80 and lysed in 1 ml (v/w) lysis buffer (50 mM NaH₂PO₄, pH 8, 300 mM NaCl, 10 mM Imidazole, 0.1% NP-40, 5 mM β-mercaptoethanol) by bead beating (2 × 6500 rpm for 40 s, MagNA lyzer cell homogenizer) using 0.5 ml 100 µM glass beads per 1.5 ml of cell suspension. The lysate was cleared by centrifugation at 14 krpm for 20 min and incubated overnight at 4°C with 0.5 ml equilibrated Ni-NTA resin (Qiagen). The resin was then loaded onto a gravity-flow column and washed with 40 column volume of wash buffer (50 mM NaH₂PO₄, pH 8, 300 mM NaCl, 20 mM Imidazole, 0.1% NP-40, 5 mM β-mercaptoethanol). The column was then washed with four column volume wash buffer containing 40 mM imidazole and four column volume wash buffer containing 50 mM imidazole. The protein was eluted by incubating the column twice with elution buffer (50 mM NaH₂PO₄, pH 8, 300 mM NaCl, 500 mM Imidazole, 0.1% NP-40, 5 mM β-mercaptoethanol). Elution fraction containing VapC toxin was dialysed for 6 h against PBS containing 1 mM DTT and overnight against PBS containing 50% glycerol and 1 mM DTT at 4°C.

Detection of *in vitro* RNA cleavage by Northern blotting analysis
*M. smegmatis* total RNA was purified using the FastRNA blue kit (see previous section). To ensure high quality, RNA was purified by an additional step of phenol/chloroform extraction. Total RNA from *M. tuberculosis* H37Rv was a generous gift from Douglas Young and Rachel Lai (National Institute for Medical Research, London and Imperial College London, UK). For the cleavage reaction 1 µg or 2.5 µg of total RNA was mixed with 1 µg or 2 µg of purified VapC4-HTF VapC11-HTF, VapC28-HTF or VapC37-HTF in cleavage buffer (final: 10 mM HEPES pH7.5, 15 mM KCl, 10 mM MgCl₂, 1 mM DTT and 25% glycerol).
and left to incubate at 37°C for 30 min. As a control VapC toxin was omitted in some reactions and Mg2+ chelated by the addition of 25 mM EDTA. The cleavage reactions were terminated by addition of FD-loading buffer and the RNA separated on an 8% Urea polyacrylamide gel buffered with 1× TBE. The RNA was transferred to a Zeta- Probe membrane and the RNA of interest detected using a radiolabelled probe as previously described.

Mapping of VapC4, VapC11, VapC28 and VapC37 cleavage site by primer extension analysis

The cleavage reactions were set up as previously described, using total RNA (4 μg) with or without 2 μg of purified VapC4-HTF, VapC11-HTF, VapC28-HTF or VapC37-HTF. The cleavage reactions were then incubated for 30 min at 37°C in cleavage buffer. The reaction was terminated by addition of 400 μl 100 mM Na-acetate pH 4.5 followed by phenol/chloroform extraction and ethanol precipitation. The precipitate was washed with 70% ethanol, air dried and dissolved in nuclease free dH2O. The reverse transcription was performed by setting up a hybridization reaction containing 0.2 pmol radiolabelled KW-MS-PXT-CysGCA-rv, KW-MS-PXT-TrpCCA-rv, KW-MS-PXT-SerTGA-S1-rv or KW-MS-PXT-LeuCAG-S-rv oligonucleotide and 1 μg of purified cleaved RNA in nuclease free dH2O. The oligonucleotide (4 pmol) was phosphorylated using 30 μCi γ 32P-ATP and T4 Polynucleotide kinase (Fermentas) and subsequently desalted using G-25 desalting columns (GE healthcare). The hybridization reactions were incubated at 80°C for 5 min and transferred to an icebath and left to incubate for 5 min. To the chilled reaction 1× FS buffer (Invitrogen), 10 mM DTT and 1 mM dNTP was added and the tube transferred to 54°C to incubate for 2 min. Then 20 U of Superscript III reverse transcriptase (Invitrogen) was added and the tubes left to incubate for 1 h. The reaction was terminated by addition of an equal volume of FD-loading buffer. The reactions were loaded onto a 10% polyacrylamide gel containing 8 M urea and 1× TBE. Along with the reverse transcription reactions a dyeoxy sequencing ladder was loaded which had been made from a PCR template generated using oligonucleotides KW-MS-PXT-CysGCA-f and KW-MS-PXT-CysGCA-rv, KW-MS-PXT-TrpCCA-rv and KW-MS-PXT-TrpCCA-f, KW-MS-PXT-SerTGA-S1-rv and KW-MS-PXT-SerTGA-f or KW-MS-PXT-LeuCAG-S-rv and KW-MS-PXT-LeuCAG-f. After the cDNA had been separated, the gel was dried and the bands visualized by phosphorimaging.

RESULTS

Identification of cellular VapC targets using CRAC

We implemented CRAC to systematically identify the cellular targets of VapC RNases from M. tuberculosis, using M. smegmatis as a surrogate host organism. CRAC identifies RNAs that interact directly with a tagged bait protein in living cells and potentially detects both stable and relatively transient interactions (26,28). To apply the CRAC protocol, all 48 vapC genes of M. tuberculosis H37Rv (Figure 1A) were cloned into plasmid pMEND-HTF downstream of a tetracycline inducible promoter and in frame with a dual affinity tag that introduced a hexaHis, TEV protease cleavage site, and 3× FLAG tags at the C-termini (HTF-tag). Figure 1B shows the effect of transcriptional induction of selected vapC genes. Expression of VapC4, 11, 25, 26, 28, 29, 30, 33, 37 and 39 strongly inhibited cell growth, whereas expression of VapC15 and 32 had a more moderate effect (for the results of phenotypic testing of all 48 VapCs, see Supplementary Figure S1A). The pattern of growth inhibition was generally consistent with previous tests in which native VapCs were expressed in M. smegmatis (8,29). The only exception was VapC32 that did not significantly reduce cell growth in our experimental system (Figure 1B). Thus, we can conclude that the C-terminal HTF tag does not interfere with VapC-mediated inhibition of cell growth by the toxins selected in this study.

The majority of VapCs expressed in M. smegmatis showed weak or no inhibition of growth (Supplementary Figure S1A). Therefore, we determined the expression levels of a number of these VapCs (Supplementary Figure S1B). We found that in some cases, including VapC41, 43 and 44, no VapC expression was detectable 60 min after induction that could explain the lack of growth inhibition. However, for the majority of non-toxic VapCs that we tested, i.e. VapC6, 10, 12, 19, 31 and 47, protein expression was detectable, indicating that the proteins either are not functional (e.g. the cellular target could be missing in the heterologous host). Alternatively, their biological functions do not entail inhibition of cell growth.

Cultures of M. smegmatis MC155 were pulsed with HTF-tagged VapC and were UV-irradiated to covalently crosslink VapCs to their target RNAs in vivo (Figure 1C). The covalently bound VapC-RNA complexes were then purified using M2 anti-FLAG resin, eluted by TEV-cleavage, and RNAs were trimmed to allow ‘footprinting’ of the protein interaction site. Trimmed VapC-RNA complexes were bound to Ni-NTA resin and barcoded linkers were ligated to the 5’ and 3’ termini. Linker-ligated RNA–protein complexes were eluted and size-selected using SDS-PAGE. Protein-RNA complexes of the appropriate molecular weight were extracted and protease digested. cDNAs were generated by RT-PCR, subjected to deep sequencing and reads were mapped to the M. smegmatis genome. VapC binding sites were initially identified using the py-CRAC software package to identify transcripts bound by each VapC. We used duplicate controls (pMEND::HTF) to assess the background of the assay. CRAC data from samples expressing different VapCs were obtained from single experiments. The results are shown as reads per million allowing us to visually compare for significance across samples.

In the following section, we describe the identification of the cellular targets of previously uncharacterized VapCs. We will refer to RNA interactions that were confirmed to confer RNA cleavage as ‘productive interactions’, and other interactions as ‘unproductive interactions’.

All six VapCs interact with a subset of tRNAs, SRP RNA and 23S rRNA

Analysis of CRAC data for VapC4, 11, 28, 29, 30 and 37 each revealed enrichment for tRNA5 Thr-GGT,
tRNA8Met-CAT, tRNA12Val-CAC, tRNA37Asn-GTT and tRNA31Asp-GTC (Supplementary Figure S2A-E) (the tRNA nomenclature used is in accordance with GtRNAdb: http://gtrnadb.ucsc.edu and the reads have been plotted as per million). However, we were unable to demonstrate that any of these tRNAs were cleaved by the respective VapCs when expressed in M. smegmatis cells (Supplementary Figure S2H-L). The CRAC analysis also revealed enrichment for SRP RNA and 23S rRNA (Supplementary Figure S2F and S2G). However, these interactions could not be confirmed as productive as no cleavage by any of the VapCs was observed (Supplementary Figure S2M and S2N). VapC28 and VapC29 did indeed showed higher enrichment with the 5’-end region of 23S rRNA (Supplementary Figure S2G) but we were not able to confirm cleavage in this region of 23S rRNA (Supplementary Figure S2O). As none of these RNA species were cleaved by VapC4, 11, 28, 29, 30 and 37 we categorize these interactions as unproductive and they were not studied further.

VapC4 specifically cleaves tRNA44Cys-GCA in M. smegmatis

Analysis of specific RNA interaction with VapC4 using CRAC revealed strong enrichment for RNA fragments mapping to tRNA44Cys-GCA (Figure 2A). The interaction with tRNA44Cys-GCA was productive as the full-length tRNA decreased upon induction of vapC4 simultaneous with the accumulation of a smaller cleavage product (compare lanes 1 and 2 with 3 and 4 in Figure 2B). We also observed weak cleavage of tRNA44Cys-GCA before induction of vapC4. This observation can be explained due to ‘leaky’ transcription initiation from the tetracycline inducible promoter as no cleavage is observed in the control. Induction of the other vapC toxins did not affect tRNA44Cys-GCA stability (lanes 5–14). The tRNAs; tRNA23Pro-CGG and tRNA32Phe-GAA were also specifically enriched by VapC4 (Supplementary Figure S3A and S3B, respectively) but none of these tRNA species were cleaved by VapC4 (compare lanes 1 and 2 in Supplementary Figure S3D andS3E, respectively). The other cysteine-accepting tRNA of M. smegmatis, annotated as tRNA40Cys-GCA, was not enriched by VapC4 in the analysis, and was not investigated further (Supplementary Figure S3C).

To confirm that the observed cleavage of tRNA44Cys-GCA was direct, cleavage was investigated in vitro by Northern analysis using purified VapC4-HTF in a reaction containing total RNA from M. smegmatis. Indeed we observed cleavage of tRNA44Cys-GCA only in the presence of VapC4 (Figure 2C). Consistent with the VapC PIN domain coordinating Mg2+ in the active site, addition of EDTA to the reaction abolished cleavage. Mapping of the cleavage site in tRNA44Cys-GCA by primer extension analysis revealed cleavage in the anticodon loop between bases C34\(\rightarrow\)A35, A35\(\rightarrow\)A36, A36\(\rightarrow\)A37 and A37\(\rightarrow\)G38 (arrows indicate cleavages between numbered nucleotides), with the A36\(\rightarrow\)A37 site being the dominant cleavage site (Figure 2D and E). The reverse transcriptase weakly terminated at this site before addition of VapC4, probably due to modification of the corresponding base.

VapC4 has recently been suggested to cleave tRNA2Ala-TGC, tRNA24Ser-GGA, tRNA26Ser-GCT of M.
and tRNA28Ser-CGA. However, stable, discrete cleavage
ments derived from tRNA25Ser-TGA, tRNA28Ser-CGA (Com-

VapC4, VapC11, VapC28 and VapC37 cleave orthologous
tRNAs in M. tuberculosis
The above-described in vitro cleavage reactions were per-
formed using total RNA from M. smegmatis as the sub-
strate. Even though the tRNAs of M. smegmatis are almost
identical to the orthologous tRNAs of M. tuberculosis there
are nucleotide differences that potentially could affect VapC
recognition and cleavage (Supplementary Figure S6A–G).
The VapC cleavage reactions were therefore also analysed

Nucleic Acids Research, 2016, Vol. 44, No. 20 9865
using total RNA of *M. tuberculosis* H37Rv. Consistent with our results in *M. smegmatis*, VapC4 cleaved tRNA21^Cys-GCA* (Figure 6A, lanes 2 and 3), VapC11 specifically cleaved tRNA3^Leu-CAG* (Figure 6B, lane 2), VapC28 specifically cleaved tRNA25^Ser-TGA* and tRNA28^Ser-CGA* (Figure 6C and D, lane 5) and VapC37 specifically cleaved tRNA7^Trp-CCA* (Figure 6E, lane 8). The cleavages were tRNA-specific and all cleavages were also inhibited by the EDTA addition, indicating Mg$^{2+}$ dependence (Figure 6B–E). These results confirmed that heterologously expressed VapCs have identical cleavage specificities in *M. smegmatis*, validating this organism as a useful surrogate host for the analysis of VapC toxins from *M. tuberculosis*.

**Phylogeny can predict novel VapC targets**

The identification of novel VapC targets is challenging and in the past required the application of laborious ‘trial-and-error’ approaches. Since *M. tuberculosis* has at least 48 different VapCs (Figure 1A), we tested the possibility that the targets we had identified could provide insights into the targets of related VapC toxins using a phylogenetic approach.
From the phylogenetic tree shown in Supplementary Figure S1C, we selected six VapCs that group together with one of the VapCs with a known target, identified here or in our previous analysis (22), and tested whether these VapCs cleaved the same targets. The following examples showed that this approach was effective.

(i) VapC15 and VapC32 cleave tRNA3Leu-CAG. VapC15 and VapC32 group together with VapC11 in the phylogram (Figure 7E and Supplementary Figure S1C). Therefore, we asked if these two VapCs also cleave tRNA3Leu-CAG, the tRNA that was cleaved most efficiently by VapC11. Indeed tRNA3Leu-CAG was cleaved upon induction of vapC15 and vapC32 (Figure 7A, lanes 3 - 6). These cleavages were relatively weak compared to those of VapC11, consistent with the lower toxicity of these VapCs in M. smegmatis (Figure 1B). VapC11 was also found to have productive interactions with tRNA13Leu-GAG and tRNA10Gln-CTG, but these tRNA species were not cleaved by VapC15 or VapC32 (Supplementary Figure S7A and S7B).

(ii) VapC25, 33 and 39 cleave tRNA7Trip-GCA. VapC25, 33 and 39 group together with VapC29 and 37 in the phylogram (Figure 7E and Supplementary Figure S1C) and induction of these toxins in M. smegmatis inhibited cell growth (Figure 1B). Notably, induction of vapC25, 33 or 39 resulted in cleavage products identical to those of VapC29 and 37 (Figure 7B lanes 3 - 8).

(iii) VapC26 cleaves 23S rRNA in the Sarcin–Ricin Loop (SRL). VapC26 groups with VapC29 in the phylogram (Figure 7E and Supplementary Figure S1C) and inhibited growth of M. smegmatis very efficiently (Figure 1B). Since VapC26 cleaves 23S rRNA in the SRL loop (22), we tested if VapC26 also cleaves 23S rRNA. Indeed, induction of vapC26 resulted in a 23S rRNA cleavage pattern identical to that of VapC26 showing that the two VapCs have identical targets (Figure 7C, lanes 3–6).

VapCs are highly target-specific

The above results indicated that VapCs grouping together phylogenetically exhibit identical RNA cleavage specificities (Figure 7E and Supplementary Figure S1C). Therefore, we analysed whether VapCs from one phylogenetic subgroup would cleave RNAs targeted by a different VapC subgroup.
As seen from both in vivo (see overview in Supplementary Figure S8A–G) and in vitro cleavage assays (see overview in Supplementary Figure S9A–D) we observed no cross-reactivity and conclude that the VapCs analysed are highly specific endoribonucleases.

**DISCUSSION**

Using CRAC in combination with phylogenetic analysis and in vivo and in vitro RNA cleavage assays, we identified the cellular targets of 12 novel VapCs from *M. tuberculosis* H37Rv. UV-crosslinking and high throughput sequencing revealed binding sites that were both produc-
The age of tRNATrp-CCA by VapC25, VapC33 and VapC39 was detected by pMEND mapped previously (22). The full-length 23S rRNA (3164 nt) is also in M. smegmatis strain MC2155 containing plasmids pMEND.

Northern analysis was performed on RNA purified from

Figure 7. Phylogeny can predict cellular VapC targets. (A) Detection of in vivo cleavage of tRNA3Leu-CAG by VapC15 and VapC32 by Northern analysis was performed as in Figure 3 (D); VapC expression was induced from plasmid pMEND::vapC15::HTF by VapC25, VapC33 and VapC39 was detected by Northern analysis performed as in Figure 5 (B). Toxin expression was induced from plasmid pMEND::vapC25::HTF, pMEND::vapC33::HTF and pMEND::vapC39::HTF. (B) in vivo cleavage of tRNA3Leu-CAG by VapC15, VapC32 and VapC39 detected by Northern analysis was performed on RNA purified from M. smegmatis strain MC2155 containing plasmids pMEND::vapC25::HTF, pMEND::vapC33::HTF and pMEND::vapC39::HTF. (C) Cleavage of 23S rRNA detected by Northern analysis was performed on RNA purified from M. smegmatis strain MC2155 containing plasmids pMEND::vapC25::HTF and pMEND::vapC33::HTF and pMEND::vapC39::HTF. Cell samples were collected before (indicated by 0) and after 120min of induction (indicated by 120) and analysed as described in Materials and Methods. The arrow indicates the 276 nucleotide cleavage product of 23S rRNA generated by VapC20 and VapC26, as mapped previously (22). The full-length 23S rRNA (3164 nt) is also indicated with an arrow. (D) Region of the decoding center of 70S ribosome of Thermus thermophilus in complex with mRNA and the ternary complex of EF-Tu•Thr•tRNAThr•GDP (pdb entry: 4V5G from (31)). The Figure highlights that VapCs of M. tuberculosis cleave RNAs essential for decoding during translation. The Sarcin - Ricin Loop (SRL) of VapC11 was less efficient (Figure 3E and F) and may represent an artefact of ectopic expression of VapC11 caused by the high sequence similarity of the anticodon loops (Supplementary Figure S6B–D).

Cruz et al. recently reported cleavage of tRNA2Ala-TGC, tRNA24Ser-GGA, tRNA26Ser-GCT by VapC4 (30). In our study we did not observe enrichment of tRNA2Ala-TGC by VapC4 (Supplementary Figure S4C) and, consistently, we did not observe cleavage of this RNA when VapC4 was induced in M. smegmatis cells (Supplementary Figure S3F). We did indeed observe weak enrichment of RNA fragments from tRNA24Ser-GGA and tRNA26Ser-GCT by CRAC with VapC4 as the bait (Supplementary Figure S4E and S4F); however, no cleavage of tRNA24Ser-GGA or tRNA26Ser-GCT by VapC4 was observed (Supplementary Figure S3G and S3H) or in vitro (Supplementary Figure S3I-L). We note that the reported cleavage of tRNA2Ala-TGC, tRNA24Ser-GGA, and tRNA26Ser-GCT by VapC4 in vitro was...
only seen after highly extended incubation times only (3-12 hr. [30]), raising the possibility that these tRNAs represent low-affinity targets of VapC. Using UV-crosslinking and Northern analysis we found that VapC4 actually interacts with, and cleaves tRNA44Cys-GCA in vivo. We used a much shorter incubation time (30 min) and exclusively observed cleavage of tRNA44Cys-GCA of M. smegmatis and the orthologous tRNA21Cys-GCA of M. tuberculosis H37Rv.

In enterobacteria, TA gene modules encoding translational inhibitors promote increased survival following exposure to antibiotics or stressful conditions within macrophages (11–15,32). The biological function(s) of the multitude of vapBC modules encoded by M. tuberculosis has not yet been established. However, it is possible that cleavage of RNAs essential for translation similarly confers protection by inhibiting cell growth, as proposed previously by other groups (8,16,17,33). Consistent with this proposal, E. coli rapidly responds to oxidative stress by downregulating translation via tRNA degradation (34). It is also possible that the vapBC genes can prevent bacteriophages from spreading in cell populations by inducing so-called ‘abortive infection’ that has been described for type III TA modules also encoding inhibitors of translation (35,36).

The M. tuberculosis genome contains an unusually large expansion of TA modules that present a unique challenge for understanding their contribution to bacterial persistence in this significant human pathogen. Here we describe a new methodology to identify the cellular targets of VapC4, which we term UV-crosslinking followed by tRNA degradation (34). This method allows the identification of new targets of VapC4 and could be applicable to other type III TA systems.

SUPPLEMENTARY DATA
Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS
We thank Douglas Young and Rachel Lai (National Institute for Medical Research, London and Imperial College London, UK) for the donation of purified M. tuberculosis RNA and Ditlev E. Brodersen for critical comments on the manuscript.

FUNDING
