ABSTRACT: Relaxation and dephasing of hole spins are measured in a gate-defined Ge/Si nanowire double quantum dot using a fast pulsed-gate method and dispersive readout. An inhomogeneous dephasing time $T^*_2 \sim 0.18 \mu s$ exceeds corresponding measurements in III–V semiconductors by more than an order of magnitude, as expected for predominately nuclear-spin-free materials. Dephasing is observed to be exponential in time, indicating the presence of a broadband noise source, rather than Gaussian, previously seen in systems with nuclear-spin-dominated dephasing.

KEYWORDS: Nanowire, spin qubit, dephasing, spin relaxation, dispersive readout

Realizing qubits that simultaneously provide long coherence times and fast control is a key challenge for quantum information processing. Spins in III–V semiconductor quantum dots can be electrically manipulated, but lose coherence due to interactions with nuclear spins. While dynamical decoupling and feedback have greatly improved coherence in III–V qubits, the simple approach of eliminating nuclear spins using group IV materials remains favorable. Carbon nanotubes have been investigated for this application but are difficult to work with due to uncontrolled, chirality-dependent electronic properties. So far, coherence has not been improved over III–V spin qubits.

Si devices have shown improved coherence for gate-defined electron quantum dots and for electron and nuclear spins of phosphorus donors. The Ge/Si core/shell heterostructured nanowire is an example of a predominantly zero-nuclear-spin system that is particularly tunable and scalable. Holes in Ge/Si nanowires exhibit large spin–orbit coupling, a useful resource for fast, all-electrical control of single spins. Moving to holes should also improve coherence because the contact hyperfine interaction, though strong for electrons associated with s-orbitals, is absent for holes associated with p-orbitals. Indeed, a suppression of electron–nuclear coupling in hole conductors was recently demonstrated in InSb.

Here, we measure spin coherence times of gate-confined hole spins in a Ge/Si nanowire double quantum dot using high bandwidth electrical control and read out of the spin state. We find inhomogeneous dephasing times $T^*_2$ up to 0.18 $\mu s$, 20 times longer than in III–V semiconductors. This time scale is consistent with dephasing due to sparse $^{75}$Ge nuclear spins. The observed exponential coherence decay suggests a dephasing source with high-frequency spectral content, and we discuss a few candidate mechanisms. These results pave the way toward improved spin–orbit qubits and strong spin-cavity coupling in circuit quantum electrodynamics.

Ge/Si core/shell nanowires host a tunable hole gas in the Ge core (Figure 1a) with typical mobility $\mu \sim 1000$ cm$^2/(V\cdot s)$. In the presence of realistic external electric fields, the one-dimensional (1D) hole gas is expected to occupy a single Rashba-split subband with $\sim 1$ meV spin–orbit splitting, based on theory and previous experiments. Fabrication of double dots with discrete hole states and measurements of spin relaxation have been reported.

The device, diagrammed in Figure 1b, is fabricated on a lightly doped Si substrate. The substrate, insulating at $T < 10$ K, is covered with HFO$_2$ using atomic layer deposition. Nanowires are deposited from methanol solution and contacted by evaporating Al following a buffered hydrofluoric acid dip. A second layer of HFO$_2$ covers the wire, and Cr/Au electrostatic gates are placed on top. These gates tune the hole density along the length of the wire. All data are obtained at temperature $T < 100$ mK in a dilution refrigerator with external magnetic field $B = 0$, unless otherwise noted.

Gate voltages are tuned to form a double quantum dot in the nanowire with control over charge occupancy and tunnel rates. High-bandwidth (400 MHz) plunger gates $V_L$ and $V_H$ labeled in Figure 1c control hole occupation in the left and right dots. The readout circuit is formed by wire bonding a 180 nH inductor directly to the source electrode of the device.

Combined with a total parasitic capacitance of 0.2 pF, this forms an LC resonance at 830 MHz with bandwidth 15 MHz. Tunneling of holes between dots or between the right dot and lead results in a capacitive load on the readout circuit, shifting its resonant frequency.\(^{36,37}\) The circuit response is monitored by applying near-resonant excitation to the readout circuit and recording changes in the reflected voltage, \(V_{RF}\), after amplification at \(T = 4\) K and demodulation using a 90° power splitter and two mixers at room temperature.

The charge stability diagram of the double dot is measured by monitoring \(V_{RF}\) at fixed frequency while slowly sweeping \(V_L\) and \(V_R\) (Figure 1d). Lines are observed whenever single holes are transferred to or from the right dot. Transitions between the left dot and left lead are below the noise floor (not visible) because the LC circuit is not connected to the right lead. Enhanced signal is observed at the triple points, where tunneling is energetically allowed across the entire device. The observed “honeycomb” pattern is consistent with that of a capacitively coupled double quantum dot.\(^{39}\) The charging energies for the left and right dots are estimated 1.7 and 2.7 meV from Figure 1d, using a plunger lever arm of 0.3 eV/V, determined from finite bias measurements on similar devices.\(^{34}\) The few-hole regime was accessible only in the right dot, identified by an increase in charging energy. On the basis of the location of the few-hole regime in the right dot, we estimate the left and right hole occupations to be 70 and 10 at the studied tuning. Positive slopes are due to hole transfers directly between dots. Guides to the eye (dashed lines) indicate hole transfers between the left dot and lead, too faint to be visible in the data because the resonator is on the right side.

The spin state of the double dot is in the \((m + 2, n + 1)\) charge state, assuming that \((m, n)\) paired holes occupy lower orbitals in the left (right) dot. Pulsing to \(P\) (“prepare”) in \((m + 1, n + 1)\) discards one hole from the left dot, leaving the spin state of the double dot in a random mixture of singlet and triplet states. Moving to \(M\) (“measure”) adjusts the energy detuning between the dots, making interdot tunneling favorable. When \(M\) is located at zero detuning, \(\epsilon = 0\), tunneling is allowed for singlet but Pauli-blocked for triplet states. When \(M\) is at the singlet–triplet splitting, \(\epsilon = \Delta_{ST}\), triplet states can tunnel. The location of the interdot charge transition therefore reads out the spin state of the double dot. We expect this picture to be valid for multihole dots with an effective spin-(1/2) ground state.\(^{35,40–42}\) We use singlet–triplet terminology for clarity but note that strong spin–orbit coupling changes the spin makeup of the blockaded states without destroying Pauli blockade.\(^{43}\)

The fast pulse sequence \(E_1 \rightarrow E_2 \rightarrow P \rightarrow M \rightarrow E_1\) is repeated continuously while rastering the position of \(M = (V_L, V_R)\) near the \((m + 1, n + 1) \rightarrow (m + 2, n)\) charge transition (Figure 2). The RF carrier is applied only at the measurement point, \(M\). As shown in Figure 1d, features with negative slope are observed corresponding to transitions across the right barrier. We interpret the weak interdot transition at zero detuning accompanied by a relatively strong interdot feature at large detuning as Pauli blockade of the ground-state interdot transition (\(\epsilon = 0\)), and lifting of blockade at the singlet–triplet splitting (\(\epsilon = \Delta_{ST}\)). The strength of the \(\epsilon = 0\) interdot transition thus measures the probability of loading a singlet at point \(P\), while the strength at \(\epsilon = \Delta_{ST}\) measures the probability of loading a triplet. As a control, the Pauli blockade pulse sequence was run in the opposite direction, and no blockade was observed (see Supporting Information).

Spin relaxation is measured by varying the dwell time \(\tau_M\) at the measurement point for the counterclockwise Pauli-blockade sequence. As \(\tau_M\) increases the triplet transition weakens and the singlet transition strengthens (Figure 3a,b) due to triplet-to-singlet spin relaxation. Note that these relaxation processes have different charge characters at different measurement points. For example, at \(\epsilon = 0\) the initial charge state is \((m + 1, n)\).
Figure 3. Spin relaxation. (a) \( V_{RF} \) at the measurement point \( M = (V_L, V_E) \) of \( T_1 \) pulse sequence (arrows). The dwell time at \( M \) is \( \tau_{M} = 0.4 \mu s \). (b) Same as (a) but with \( \tau_{M} = 4 \mu s \). (c) Cuts along the \( V_E \) region indicated in (b) for \( \tau_{M} = 0.4 \mu s (\square) \) and \( \tau_{M} = 4 \mu s (\bigcirc) \). Each cut is fit with the sum of two Lorentzians, the left of height \( V_0^{(S)} \) and right of height \( V_0^{(T)} \). The center of the left Lorentzian defines zero detuning, \( V = 0 \). (d) Readout visibility \( I^{(ST)} = V_0^{(ST)}/V_0^{(S)} \) as a function of \( \tau_{M} \). Fits are to eqs 1 and 2 and have characteristic decay times \( T_1^{(S)} = 200 \text{ ns} \) and \( T_1^{(T)} = 800 \text{ ns} \) for singlet and triplet states. Normalization factors are \( V_0^{(S)} = 25 \text{ \mu eV} \) and \( V_0^{(T)} = 200 \text{ \mu eV} \).

Figure 4. Spin dephasing. (a) \( V_{RF} \) at the measurement point \( M = (V_L, V_E) \) of \( T_2^* \) pulse sequence (arrows). The dwell time at \( S \) is \( \tau_{S} = 10 \text{ ns} \). (b) Same as (a) but with \( \tau_{S} = 1 \mu s \). (c) Normalized differential voltage at the triplet line \( \Delta v \equiv [V_{RF}(S) - V_{RF}(0)]/[V_{RF}(0) - V_{RF}(S)] \) as a function of \( \tau_{S} \). The \( B = 0 \) data are measured at \( (V_L, V_E) \) indicated in (b), yielding a \( T_2^* \) dephasing time of 0.18 ms. The \( B = 1 \text{T} \) data are obtained at a different dot occupancy and tuning using the same method, yielding \( T_{2^*} = 0.15 \text{ ms} \). The normalization factor is \( V_{RF}(0) - V_{RF} = 35 \text{ \mu V} \). Solid and dashed lines are fits to exponentials. (d) Probability \( P^{(ST)} = V_0^{(ST)}/V_0^{(S)} \) obtained from data as in (a,b), analyzed as in Figure 3c. Fits are to eqs 3 and 4 with \( T_{2^*} = 0.18 \text{ ms} \) fixed from (c). Normalization factors are \( V_0^{(S)} = 60 \text{ \mu eV} \) and \( V_0^{(T)} = 130 \text{ \mu eV} \).

To investigate spin dephasing, an alternate pulse sequence is used that first initializes the system into a singlet state in \( m + 2, n \) at point \( P \), then separates to point \( S \) ("separate") in \( m + 1, n + 1 \) for a time \( \tau_S \) (Figure 4a). The spin state of the double dot is measured at \( M \) by pulsing back toward \( m + 2, n \). For short \( \tau_S \) (Figure 4a) a strong singlet return feature is observed, consistent with negligible spin dephasing. For long \( \tau_S \) (Figure 4b), a strong triplet return feature is observed, consistent with complete spin dephasing.

The \( T_2^* \) dephasing time is found by measuring \( V_{RF}(\tau_S) \) at the triplet transition, and plotting the normalized differential voltage \( \Delta v \equiv [V_{RF}(\tau_S) - V_{RF}(S)]/[V_{RF}(0) - V_{RF}(S)] \) as a function of separation time (Figure 4c). Here, \( V_{RF}(0) \equiv V_{RF}(500 \text{ ns}) \) is the demodulated voltage for a pulse sequence with long dephasing time. The quantity \( [V_{RF}(\tau_S) - V_{RF}(S)] \) is directly measured by alternating between the \( T_2^* \) sequence and a reference sequence with long dephasing time and feeding the demodulated voltage into a lock-in amplifier. Fitting the \( B = 0 \) data to \( \exp[-(\tau_S/\tau_{2^*})^\alpha] \) yields \( \alpha = 1.1 \pm 0.1 \). Figure 4c shows exponential fits (\( \alpha = 1 \)) for both data sets. The \( B = 0 \) data decays exponentially on a time scale \( T_{2^*} = 0.18 \text{ ms} \). Data acquired at \( B = 1 \text{T} \) at a different double-dot occupation give a similar time scale and functional form.

Although this time scale is approaching the limit expected for dephasing due to random Zeeman gradients from sparse \(^{75}\text{Ge}\) nuclear spins (see Supporting Information), the observed exponential loss of coherence is by and large unexpected for nuclei. A low-frequency-dominated nuclear bath is expected to yield a Gaussian falloff of coherence with time,\(^{25}\) which is in contrast to the observed exponential dependence, which instead indicates a rapidly varying bath.\(^{26}\) Nuclei can produce...
high-bandwidth noise in the presence of spatially varying effective magnetic fields, for example, due to inhomogeneous strain-induced quadrupolar interactions.\(^9\) The similarity of data at \(B = 0\) and \(B = 1\) T in Figure 4c, however, would indicate an unusually large energy-scale for nuclear effects. Electrical noise, most likely from the sample itself, combined with spin–orbit coupling is a plausible alternative. For electrons, the ubiquitous high-frequency noise source appears directly in the unexplained high-frequency noise. In our system, the high-frequency noise was removed using dynamical decoupling, revealing the presence of unexplained high-frequency noise. In our system, the effect of nuclei is reduced by the choice of material, and an unexplained high-frequency noise source appears directly in the \(T_2^*\). These similarities suggest the existence of a shared dephasing mechanism that involves spin–orbit coupling.

Unexplained high-frequency noise has recently been observed in other strong spin–orbit systems, such as InAs nanowires,\(^28\) InSb nanowires,\(^30\) and carbon nanotubes.\(^10\) In these systems, slowly varying nuclear effects were removed using dynamical decoupling, revealing the presence of unexplained high-frequency noise. In our system, the effect of nuclei is reduced by the choice of material, and an unexplained high-frequency noise source appears directly in the \(T_2^*\). These similarities suggest the existence of a shared dephasing mechanism that involves spin–orbit coupling.

Future qubits based on Ge/Si wires could be coupled capacitively\(^33,35\) or through a cavity using circuit quantum electrodynamics.\(^33,45\) In the latter case, the long dephasing times measured here suggest that the strong coupling regime may be accessible.
