INTRODUCTION

Chronic *Pseudomonas aeruginosa* lung infection is the most severe complication in cystic fibrosis (CF) patients (Koch and Høiby, 2000). The infection is characterized by biofilm aggregates of *P. aeruginosa* within the endobronchial mucus surrounded by high densities of active polymorphonuclear leukocytes (PMNs) (Bjarnsholt et al., 2009). The activity of PMNs has been shown to be the major cause of O2 depletion due to production of the reactive oxygen species superoxide (O2−) and nitric oxide (NO) within sputum samples (Kolpen et al., 2010, 2014a). Combined with the O2 consumption by lung epithelial cells, micro-oxic to anoxic conditions can develop in the airways of CF patients (Worlitzsch et al., 2002), which have been further evidenced by the upregulation of the O2 sensing anaerobic global regulator (Anr) in *P. aeruginosa* isolates (Hoboth et al., 2009) and the presence of obligate anaerobes such as *Prevotella* within sputum (Tunney et al., 2008). While O2 depletion by microbial aerobic respiration is thus diminutive, *P. aeruginosa* has been shown to be actively growing within the mucus of lungs (Kragh et al., 2014) and sputum (Yang et al., 2008). As a facultative anaerobe, this growth may be attributable to *P. aeruginosa*’s ability to perform anaerobic respiration by denitrification.

Denitrification was first described as the liberation of gaseous nitrogen oxides (N-oxides) by bacteria (Gayon and Dupetit, 1886) and involves the utilization of N-oxides as alternative electron acceptors for respiration (Figure 1). This definition of...
Denitrification means that while nitrate (NO$_3^-$) reduction to nitrite (NO$_2^-$) contributes directly to energy generation via the proton pumping action of the membrane-bound nitrate reductase (NarGHIJ) (Chen and Strous, 2013), the first step in strict denitrification is actually NO$_2^-$ reduction, where NO is the first gaseous product arising from NO$_3^-$ reduction (Zumft, 2005).

Engagement of denitrification in infected CF lungs is in accordance with the production of the denitrification intermediate nitrous oxide (N$_2$O) in sputum (Kolpen et al., 2014b), the presence of the denitrification marker OprF and antibodies against OprF in lung secretions and sera (Yoon et al., 2002), antibodies against Nar in sera (Beckmann et al., 2005) and the upregulation of the denitrification reductases in CF isolates (Son et al., 2007; Hoboth et al., 2009; Lee et al., 2011). Additionally, after antimicrobial treatment the infected sputum content of NO$_3^-$ increases (Grasemann et al., 1998) indicating a reduction in the activity of denitrifying cells.

**MATERIALS AND METHODS**

**BACTERIAL STRAINS AND PLASMIDS**

The strains and plasmids used in this study are listed in [Table 1](#). Primers used in this study are listed in [Table 2](#). The wild type strain used for experiments and reporter plasmid insertion was PAO1 obtained from the Pseudomonas Genetic Stock Center (www.pseudomonas.med.ecu.edu, strain PAO0001). The Holloway PAO1 wild type was used as the control for the examinations of the Holloway PAO1 ΔnirS-N and the Holloway PAO1 ΔnosZ mutants. The PAO1 strains grew at similar rates under anoxic conditions.

Gmr (Gentamicin resistant), Ap' (Ampicillin resistant), Mucoid (M), Non-mucoid (NM), Wild type (WT).
Plasmids containing eGFP or DsRed-Express tagged reporter genes were derived from pME as pG19nir and pG19nos plasmids carrying deletion cassettes of nirS to nirN and nosZ were constructed with the same procedure described previously (Maseda et al., 2004). The pG19II-derived plasmids were transferred into Holloway PAO1 by conjugation with E. coli S17-1 (Simon et al., 1986) followed by homologous recombination described elsewhere (Maseda et al., 2004). The mutants were analyzed by polymerase chain reaction (PCR) (Toyofuku et al., 2013).

The eGFP-based reporter probe plasmid, pMEXGFP, was constructed as described previously (Toyofuku et al., 2013). The promoter regions of narK1 and norC were amplified with pNarK1 F/pNarK1 R or pNorC F/pNorC R primer pairs and cloned into pMEXeGFP for promoter activity assays. pMEXdsREDex was constructed in the same way, with dsredexpress amplified using the primer pairs GfpF1/dsredR1 (Table 2) and post subcloning, the primer pair pET15b-kpn/dsredR2 (Table 2) was used to amplify a RBS-fused DsRed-Express to clone into the pME9 plasmid (Toyofuku et al., 2007). The promoter regions of nirS and nosR were amplified with the primer pairs pNirS F/pNirS R or pNosR F/pNosR R (Table 2) and cloned into the pMEdsREDex for promoter activity assays.

The reporter plasmid insertion was achieved by preparation of electro-competent cells as previously described (Choi et al., 2005) and subsequent electroporation at 25 μF, 200 Ω, 2.5 kV with 1 μl of plasmid DNA for 100 μl of electro-competent cells. Transformed cells were selected for by plating with 30 ng ml−1 of gentamicin (Sigma-Aldrich, St. Louis, MO, USA) and frozen cultures were produced from a single colony.

Clinical strains (5 mucoid and 7 non-mucoid) were isolated from expectorated sputum of 7 chronically infected CF patients (Kolpen et al., 2014b).
growth rate of 0.7 divisions h\(^{-1}\) and final OD\(_{600}\) of 1.0 (data not shown) corresponded well with previously reported growth rates of \textit{P. aeruginosa} (Alvarez-Ortega and Harwood, 2007; Lee et al., 2012; Fang et al., 2013).

**PROMOTER ACTIVITY—REPORTER STRAINS**

To further confirm the engagement of denitrification, the transcripts and promoter activity of the four \textit{N}-oxide reductases (\textit{Nar}, \textit{Nir}, \textit{Nor}, \textit{Nos}) were studied using qRT-PCR and fluorescent reporter strains, respectively. Reporter strains with the promoter region of the four denitrification reductase operons; \textit{narK1, K2, GHJI}, \textit{mirS, MCFLGHJEN}, \textit{norCBD}, \textit{nosRZDFYLY} (Schobert and Jahn, 2010) fused to fluorescent tags of either eGFP or DsRed-Express (Table 1) were used to study promoter activation under anoxic conditions with 400 \(\mu\)M KNO\(_3\) supplemented LB as described above.

GFP and DsRed require O\(_2\) for chromophore maturation (Craggs, 2009; Strack et al., 2010). Consequently, 1600 ng ml\(^{-1}\) chloramphenicol (Sigma-Aldrich) was added to the cultures to prevent new protein synthesis (Toyofuku et al., 2013) with shaking for 1 h at 37\(^\circ\)C in atmospheric air prior to measurement to allow the chromophore to develop—termed oxic fluorescence recovery (OFR) (Zhang et al., 2005). The signal was detected by flow cytometry as described below. The fluorescence values obtained were corrected for background fluorescence seen in the control strains with eGFP and dsRedExpress unconjugated to a promoter.

**FLOW CYTOMETRY**

Detection of reporter strain fluorescence was performed using a FACSCanto flowcytometer (BD Biosciences, San Jose, CA, USA) with a 488 nm argon laser. eGFP was detected in FL-1 with a 520 nm long pass filter and a 530/30 nm band pass emission filter. DsRed-Express fluorescence was collected in FL-2 with a 556 nm long pass filter and 585/42 nm band pass emission filter. To maximize resolution, samples were analyzed at low flow rate corresponding to 10 \(\mu\)l min\(^{-1}\). At least 10,000 events were recorded for each sample. Cytometer Setup and Tracking Beads (BD Biosciences) were used for instrument calibration, and flow data were processed and analyzed by Diva (BD Biosciences).

**DENITRIFICATION GENE TRANSCRIPT EXPRESSION—RNA EXTRACTION AND REVERSE TRANSCRIPTION**

PAO1 was grown in triplicate for 3 h under anoxia with either unsupplemented LB or LB with 400 \(\mu\)M KNO\(_3\). The 3 h time point was chosen as it represented the approximate peak of promoter activity, as seen in the reporter strains. After 3 h, the cultures were mixed with 2 volumes of RNA\(_{\text{later}}\) (Ambion, Austin, TX, USA) within the anoxic bench for transcript stabilization and kept at 4\(^\circ\)C overnight before freezing at ~80\(^\circ\)C. The cultures were subsequently thawed on ice, centrifuged to harvest the cells and lysed with 100 \(\mu\)l of 1 mg ml\(^{-1}\) lysozyme (Affymetrix, Cleveland, OH, USA) at room temperature for 13 min. Total RNA was extracted with RNaseasy Mini Kits (Qiagen Danmark, Limburg, NL) and contaminating chromosomal DNA was removed by treatment with RQ1 RNase-free DNase (Promega, Madison, WI, USA). RNA quality was detected in a NanoDrop spectrophotometer (Thermo Scientific). cDNA was synthesized from 250 to 500 ng of RNA (depending on the concentration extracted) and High Capacity RNA-to-cDNA Master Mix (Applied Biosystems, Foster City, CA, US) with a final reaction volume of 20 \(\mu\)l in a 2720 Thermal Cycler (Applied Biosystems). The conditions consisted of 5 min at 25\(^\circ\)C, 30 min at 42\(^\circ\)C, 5 min at 85\(^\circ\)C and subsequent holding at 4\(^\circ\)C. cDNA was frozen at ~20\(^\circ\)C. Negative controls contained template with the Master Mix replaced with water. cDNA was diluted 1:100 for qPCR.

**PRIMER DESIGN**

Primers for the denitrification genes \textit{narK1}, \textit{nirS}, \textit{norC}, \textit{nosR} and the reference gene \textit{rpoD} were designed using Integrated DNA Technologies Primer Quest software (http://www.idtdna.com) using sequences from the PAO1 Genome Sequence, \textit{Pseudomonas Genome Database} (Winsor et al., 2011) (Table 2).

**QUANTITATIVE PCR**

Each PCR mix had a final volume of 20 \(\mu\)l containing 10 \(\mu\)l SYBR Green qPCR Master Mix 2x (Applied Biosystems) 2 \(\mu\)l cDNA, 2 \(\mu\)l of 2 pmo1 \(\mu\)l\(^{-1}\) forward and reverse primers and 4 \(\mu\)l water. Quantitative real-time PCR was performed with a StepOnePlus,
Real-Time PCR system ( Applied Biosystems) with initial denaturation at 95°C for 10 min followed by 40 cycles of 95°C for 15 s, 60°C for 30 s and 72°C for 30 s.

Data were normalized to the expression of rpoD, a housekeeping gene encoding the primary sigma factor for RNA polymerase found to be constitutively expressed in P. aeruginosa (Savli et al., 2003). To control for variations between runs, the housekeeping and target genes for each of the three samples were amplified in one 96-well plate. Expression of the target genes in the cultures with 400 µM KNO₃ was compared to the unsupplemented cultures and the difference expressed as n-fold change.

NO₃⁻ AND NO₂⁻ QUANTIFICATION
For measuring NO₃⁻ and NO₂⁻ concentration in the culture media, the supernatant was harvested and syringe filtered through a syringe filter (TRP, Trasadingen, SUI) (pore size 0.22 µm) and frozen at −20°C for later measurement. NO₃⁻ and NO₂⁻ were detected in 96-well microtiter plates using a modified Griess nitrite/nitrate colorimetric assay (Cayman Chemicals, Ann Arbor, MI, USA) according to manufacturer’s instructions and as previously described (Kolpen et al., 2014a). Briefly, NO₃⁻ concentration was estimated by incubating with the Griess Reagent, converting NO₃⁻ into a purple azo-compound detected by absorbance at 540 nm in a Multiskan EX plate reader (Thermo Scientific). For NO₂⁻ concentration, NO₃⁻ was first converted to NO₂⁻ by incubation with NO₃⁻ reductase and subsequent addition of the Griess reagent to detect total NO₃⁻ plus NO₂⁻. The NO₂⁻ concentration was calculated as the difference between the total NO₂⁻ and NO₃⁻ concentration and the NO₂⁻ concentration. The detection limit of the assay was ~2 µM for NO₂⁻ and ~5 µM for NO₃⁻.

MICROSENSOR MEASUREMENTS OF N₂O
Additionally, reductase activity was elucidated by measuring consumption of NO₃⁻ and production of NO₂⁻ as well as measurements of N₂O gas accumulation in a ΔnosZ mutant strain incapable of the final reduction step in denitrification of N₂O to N₂. Each small glass vial (Schuett Biotec, Göttingen, DE) containing anoxic planktonic cultures of either PAO1 WT or the ΔnosZ mutant were placed in a 37°C heated rack and kept sealed prior to individual measurements, upon which they were shaken and the lid removed. Immediately after, N₂O was detected in the media using an amperometric N₂O microsensor (Andersen et al., 2001) with a tip diameter of 25 µm (Unisense A/S, Aarhus, DK) as previously described (Kolpen et al., 2014a). Each measurement consisted of a 5 s wait period followed by 5 s measurements taken at 7, 1 mm intervals with data acquisition and sensor positioning controlled by the Sensortrace Pro 2.0 (Unisense A/S) dedicated software. Mean experimental N₂O concentration was calculated from triplicates of three individual experiments. The final mean was corrected for the background signal detected in pure LB.

STATISTICAL ANALYSIS
Data was analyzed for statistical significance with Prism 4 software (GraphPad Software, Inc., La Jolla, CA, USA). Unless otherwise mentioned, parametric data was analyzed by One-Way ANOVA with Dunnett’s multiple comparison test and non-parametric by Friedman’s test with Dunn’s multiple comparison. P < 0.05 was considered significant.

RESULTS
DENITRIFICATION HAS A SIGNIFICANT ROLE IN ANOXIC GROWTH OF PAO1 AND CLINICAL ISOLATES AT PHYSIOLOGICAL LEVELS OF NO₃⁻
The specific growth rates of P. aeruginosa grown for 20 h in anoxic LB supplemented with physiologically relevant concentrations of NO₃⁻ (0–1 mM of NO₃⁻) were calculated. PAO1 (Figure 2A) and 12 clinical isolates (5 mucoid and 7 non-mucoid) (Figure 2B) displayed a significant increase in specific growth rate as compared to the unsupplemented control at ≥150 µM NO₃⁻ (p = 0.0138) and ≥100 µM (p = 0.0132) NO₃⁻, respectively. Despite the considerable variation between the growth rates of the clinical isolates, there was no significant correlation with the duration of infection as well as no significant difference between the growth rates of the mucoid and non-mucoid clinical isolates.

![Figure 2](image-url)
The suitability of the assay was demonstrated in a pilot study with anoxic cultures of PAO1 supplemented with 100 mM NO$_3^-$, where our measured growth rate of 0.7 divisions h$^{-1}$ and final OD$_{600}$ of 1.0 (data not shown) corresponded well with previously reported growth rates of $P.$ aeruginosa (Alvarez-Ortega and Harwood, 2007; Lee et al., 2012; Fang et al., 2013).

To discern the portion of growth attributable to denitrification, we compared the specific growth rates in anoxic cultures supplemented with NO$_3^-$ of the WT to a ΔnirS-N mutant, which is able to reduce NO$_3^-$ to NO$_2^-$, but with a blocked first step of strict denitrification due to the inability to reduce NO$_2^-$ to NO, under the same growth conditions were estimated (Figure 3A). NO$_3^-$ supports modest growth of the ΔnirS-N mutant with increasing NO$_3^-$ supplementation in accordance with Nar's contribution to proton motive force generation (Chen and Strous, 2013), but with a significant reduction in growth as compared to the WT at NO$_3^-$ ≥400 μM (p = 0.0316). One mM NO$_3^-$ was required to initiate a significant increase in growth rate from the unsupplemented control in the ΔnirS-N mutant (p = 0.0021). The consumption of NO$_3^-$ and the accumulation of NO$_2^-$ in the sterile filtered growth media of the ΔnirS-N mutant at 20 h confirmed that the ability to reduce NO$_3^-$ to NO$_2^-$ was present in the ΔnirS-N mutant, but that the mutant failed to further reduce NO$_2^-$ as opposed to the total consumption of NO$_2^-$ by the WT. Furthermore, we demonstrated very low concentrations of NO$_3^-$ and NO$_2^-$ pre-inoculation in LB and that the concentration of NO$_2^-$ was not affected by NO$_3^-$ (Figures 3B,C).

**DYNAMIC INCREASE IN DENITRIFICATION REDUCTASE PROMOTER ACTIVATION AT 400 μM NO$_3^-$**

The reporter strains were grown under anoxia for 20 h supplemented with 400 μM NO$_3^-$ and the fluorescence measured post chloramphenicol addition with OFR by flow cytometry (Figure 4). The activity of all four promoters was significantly increased during supplementation with 400 μM NO$_3^-$, but the time course varied. The Nar activity showed a small peak at 2 h (p < 0.0001) in comparison to Nor, which showed a stronger peak at 2–3 h (p < 0.0001). Nir and Nos first showed significant upregulated promoter activity after 1 h and continued to be so over 20 h (p < 0.0001 and 0.0273). In all reductases other than the Nos, there were also periods of significant upregulation in the unsupplemented control, but for shorter periods of time and with lower peaks. The transcripts of the denitrification reductases genes in PAO1 grown under anoxia with 400 μM NO$_3^-$ after 3 h showed significant upregulation of nirS, norC and nosR (p-values = 0.014, 0.014, and 0.04) (Figure 5).

We noted that anoxic conditions alone were apparently sufficient to trigger upregulation of some denitrification reductases as previously observed in other planktonic and biofilm studies (Härtig and Zumft, 1999; Hentzer et al., 2005; Schreiber et al., 2007) and that LB is a rich medium which we found to contain ~20 μM NO$_3^-$. We speculate that this is an explanation for the observed upregulation in our unsupplemented controls. However, the focus of the present study is on the differences due to the additional physiological levels of NO$_3^-$ supplementation.
**NO\textsubscript{3}^- IS RAPIDLY CONSUMED WITH A SUBSEQUENT TRANSIENT INCREASE OF NO\textsubscript{2}^- IN ANOXIC GROWTH MEDIA**

Medium from the reporter PAO1 strains showed that 400 \( \mu \text{M} \) NO\textsubscript{3}^- was depleted to below the detection level of the Griess assay within just 2 h with a transient increase in the product of its reduction, NO\textsubscript{2}^- (Figure 6). This rapid depletion combined with the time taken to harvest the supernatant is the likely explanation for the initial time point showing somewhat less than the expected 400 \( \mu \text{M} \) NO\textsubscript{3}^- , as the media pre-inoculation was tested and confirmed to contain 400 \( \mu \text{M} \) NO\textsubscript{3}^-.

**N\textsubscript{2}O IS PRODUCED IN RESPONSE TO NO\textsubscript{3}^- SUPPLEMENTATION**

The \( \Delta \text{nosZ} \) mutant and a WT PAO1 strain were grown with physiological concentrations of NO\textsubscript{3}^- under anoxia and the average \( \text{N}_2\text{O} \) accumulation over 20 h detected. With as little as 62.5 \( \mu \text{M} \) NO\textsubscript{3}^- , a significant production of \( \text{N}_2\text{O} \) was stimulated (\( p = 0.0125 \)) (Figure 7). The WT produced <10 \( \mu \text{M} \) of \( \text{N}_2\text{O} \) at all experimental concentrations of NO\textsubscript{3}^-; confirming
Indicates a substantial additional contribution of denitrification to the observed anoxic growth of \textit{P. aeruginosa} at physiological levels of NO$_3^-$.

Anoxic growth of mutants with defective Nir was also reduced at concentrations of NO$_3^-$ greater than physiological levels [10 mM (Schreiber et al., 2007) and 100 mM (Filiatrault et al., 2006)].

In addition to supporting anoxic growth, Nir may promote the persistence of \textit{P. aeruginosa} in the infected CF lungs as Nir is required for type III secretion resulting in prolonged survival in human monocytes (Van Alst et al., 2009) and enhanced virulence (Filiatrault et al., 2006). This supports the idea that denitrification is necessary for achieving the observed growth of \textit{P. aeruginosa} in the lungs.

The dynamic increase in the promoter activity of all four denitrification reductases over 20h and increased expression of all transcripts but the \textit{narK} at 3h with 400 \( \mu \)M NO$_3^-$ further emphasized the engagement of denitrification. The explanation for the transient peak in Nar expression and lack of upregulation at 3h became apparent after analysing the growth media for NO$_3^-$ content, showing depletion after just 2h. Expression of Nar is controlled in part by the two-component NO$_3^-$-sensing regulator NarX-L (Schreiber et al., 2007; Schobert and Jahn, 2010) so presumably after NO$_3^-$ depletion Nar expression is no longer induced. The Nor is also proposed to be under NarX-L control (Schobert and Jahn, 2010), which would explain the decrease in promoter activity after 2h.

The Nar and Nox$_3$ displayed a transient increase in the growth media which was similarly rapidly depleted by 3h. However, the expression of Nir and Nos appeared to be less tightly regulated by NO-oxide concentration as they were still significantly upregulated at 20h, and in the case of the Nir, only a modest increase in expression was stimulated by NO$_3^-$ supplementation. The additional O$_2$-sensing Anr regulator and downstream NO sensing dissimilative nitrate respiration (Dnr) regulator (Schreiber et al., 2007; Schobert and Jahn, 2010; Trunk et al., 2010; Arai, 2011) plays a more important role in Nir and Nos regulation (Schreiber et al., 2007; Schobert and Jahn, 2010) and hence their expression more responsive to the anoxic conditions and the downstream denitrification product NO resulting in prolonged increase in expression.

As N-oxides are not exclusively utilized in strict denitrification—NO$_3^-$ reduction is also able to feed into dissimilatory pathways for ammonia excretion or into assimilatory pathways for incorporation into biomolecules (Zumft, 1997)—we also studied NO$_2$O production. The known pathways for NO$_2$O production are denitrification and nitrification via oxidation of hydroxylamine to NO$_2$O (Khalila et al., 2004). As of yet, there is no evidence to suggest that \textit{P. aeruginosa} performs or possesses homologs of the enzymes required for nitrification [PAO1 Genome Sequence, Pseudomonas Genome Database (Winsor et al., 2011)]. Additionally, the process requires O$_2$ (Meyer et al., 2008) and thus for our anoxic experiments we assumed that all detected NO$_2$O was produced via the denitrification pathway and therefore acted as a specific marker. In the \textit{P. aeruginosa} nitrous oxide reductase mutant \textit{ΔnosZ}, unable to reduce NO$_2$O to N$_2$, we found a significant accumulation of NO$_2$O in the anoxic growth media with as little NO$_3^-$ supplementation as 62.5 \( \mu \)M. This finding further supports that \textit{P. aeruginosa} employs denitrification to facilitate anoxic growth.

\textbf{DISCUSSION}

\textit{P. aeruginosa} is able to thrive under anoxic conditions by performing denitrification. Our initial studies performed with clinical isolates and PAO1 under anoxic conditions showed that physiological concentrations of NO$_3^-$ are sufficient to support a significant increase in growth rate, even in cultures supplemented with less NO$_3^-$ than the 400 \( \mu \)M applied by Palmer et al. (2007).

The anoxic growth rates obtained are comparable to those reported in CF lungs and sputum, except for the very low growth rates in some of the clinical samples from CF lungs and sputum (Yang et al., 2008; Kragh et al., 2014). This is likely due to our planktonic studies representing a slightly faster growth rate as the shaken cells have equal access to nutrients in the media, whereas in the biofilm mode of growth in the lungs, internal cells are assumed to have access to less nutrients, including NO$_3^-$, due to diffusion limitation and utilization by cells at the periphery of the biofilm (Bjarnsholt et al., 2009). Additionally, ~10% of the cells in clinical samples appear to be in stationary phase (Yang et al., 2008) whereas the growth rates in our experiments are calculated from the exponential growth phase. In the lungs, \textit{P. aeruginosa} is also under continual attack from the host inflammatory response and antibiotic stress (Hoiby, 2006), which is also likely to reduce the rate of growth.

Nar is required for anoxic growth at physiological levels of NO$_3^-$ in CF sputum (Palmer et al., 2007) and accordingly NO$_3^-$ reduction alone is able to generate some growth as seen in the \textit{ΔnirS-N} mutant, unable to perform the subsequent NO$_3^-$ reduction and therefore blocking denitrification. However, we demonstrate that the \textit{ΔnirS-N} mutant requires the highest physiological concentration of 1 mM NO$_3^-$, seen only in exacerbated CF patients following antimicrobial treatment (Grasemann et al., 1998), to enable a significant increase in growth rate as well as a significant reduction of growth as compared to the WT. This indicates a substantial additional contribution of denitrification to the observed anoxic growth of \textit{P. aeruginosa} at physiological levels of NO$_3^-$.
obtain energy for growth at physiological levels of NO$_3^-$ in anoxic conditions.

Interestingly, one late clinical strain isolated from a patient chronically infected for 35 years, was unable to grow in anoxic conditions with NO$_3^-$. This may relate to adaptations of more flexible nitrate metabolism over time, with denitrification suggested to no longer be essential for growth for some strains at later phases of infection (Oberhardt et al., 2010; Cramer et al., 2011). While NO$_3^-$ was unable to stimulate anoxic growth of the late isolate, alternative anoxic growth may occur by arginine fermentation (Vander Wauwen et al., 1984) and survival could be facilitated by pyruvate fermentation (Eschbach et al., 2004) and phenazine redox cycling (Glasser et al., 2014; Quinn et al., 2014). Alternatively, the late isolate may have adapted to favor growth in the alveoles where oxygen is supplied by inspired air and capillaries surrounding the alveoles (West, 2000).

It has previously been shown that micro-oxic conditions are able to support growth of _P. aeruginosa_ (Alvarez-Ortega and Harwood, 2007). Here we substantiate that physiological concentrations of NO$_3^-$ are also able to support growth by denitrification in anoxic conditions, highlighting the flexibility of _P. aeruginosa’s_ ability to survive in a range of environments in the CF airways (Worlitzsch et al., 2002; Aanaes et al., 2011; Kolpen et al., 2014a). Interestingly, physiological concentrations of NO$_3^-$ may also enhance growth of _P. aeruginosa_ even at micro-oxic conditions since a growth advantage of laboratory strains carrying a lasR mutation, which is associated with severe lung damage in infected CF patients (Hoffman et al., 2009), was obtained with supplementation of only 125 µM NO$_3^-$ in conditions with limited O$_2$ mass-transfer (Hoffman et al., 2010).

In conclusion, _P. aeruginosa_ is readily able to adapt to the physiological levels of NO$_3^-$ and lack of O$_2$ in the infected CF lungs by employing denitrification. The ability of _P. aeruginosa_ to grow under anaerobic has clinical relevance as multiple classes of antibiotics are known to have reduced efficacy in the absence of O$_2$ (Walters et al., 2003; Dwyer et al., 2014). Denitrification may consequently be a major factor in _P. aeruginosa’s_ observed tolerance to antibiotic treatment in CF patients (Hoiby et al., 2010). This tolerance may be overcome by directing antibacterial treatment against denitrification as suggested by the downregulation of _narG_ and _narH_ resulting in increased susceptibility of _P. aeruginosa_ to fosfomycin and tobramycin combination treatment under anoxic conditions (McCaughey et al., 2013). Denitrification has also recently been proposed to contribute to the pathogenicity of bacterial species infecting CF lungs due to its activity in _P. aeruginosa_ as well as the highly pathogenic species _Achromobacter xylosidans_ and _Burkholderia multivorans_ in comparison to the less pathogenic _Stenotrophomonas maltophilia_ which is unable to perform denitrification (Kolpen et al., 2014c). Accordingly, our results underline the importance of developing novel treatments that target _P. aeruginosa’s_ flexible metabolism more broadly, with the denitrification reductases presenting potential targets, and that can be administered to reach the varied lung microenvironments that _P. aeruginosa_ is able to adapt to and persist within.
