Abstract

Amount of vocal protest was measured in 4-month-old infants of depressed vs. non-depressed mothers during 10 minute face-to-face interaction. The sample consisted of two groups of mothers with their infants: depressed (n=17) and non-depressed (n=49). In total N=66. Vocal protest was measured using PRAAT phonetic software and manual, reliable coding. Results showed that infants of depressed mothers expressed a lower amount of vocal protest compared to infants of non-depressed mothers as measured in mean percentage of time (p < .001).

Background

A significantly heightened amount of protest has previously been reported for infants of depressed mothers during face-to-face interaction (Field, Healy, Goldstein, & Guflerz, 1990). The other studies have also reported a heightened amount of protest in infants of depressed mothers on a tendency level (Murray, Furt-Cowley, Hooper, & Cooper, 1996; Friedman, Beebe, Jaffe, Ross, & Trigg, 1996). Previous studies have predominantly used composite multimodal measures, which measure several modalities together (Field et al., 1990; Murray et al., 1996). However, multimodal measures may cover up so-called discordant affects (the infant is expressing converging affects through different modalities), which have been detected in infants of depressed mothers (Beebe et al., 2008).

Methods

Participants

The sample consisted of 66 primiparous mothers and their infants from the urban Copenhagen area with PPD group (n=17) and non-depressed group (n=49). Inclusion criteria were: Primiparous mother, healthy infant, mother at least 18 years, living in the Copenhagen area, normal hearing and vision abilities. Exclusion criteria were: Psychosis and/or presence of co-morbid bipolar disorder and abuse of any substances.

Procedure

Set-up

The interaction took place according to a standardized design of mother-infant face-to-face interaction. Mother and infant were seated in front of each other at a distance of approximately 50 cm, the infant in an infant seat and the mother on a small chair. Vocal recordings were made using individually head-mounted high quality microphones. The mother was instructed to play with their infants as she would usually do at home.

Vocal coding and reliability

Acoustic analysis and labeling was carried out using PRAAT software for phonetic analysis. The recordings were segmented into speech and non-speech intervals using a semi-automated procedure during which possible segments of speech were first identified based on intensity threshold levels. The segments were then verified and adjusted manually and infant vocalizations were reliably separated into negative (protest) and neutral-positive vocalizations by blind coders. Coders were trained to achieve reliability at minimum kappa (K) ≥ 0.60 for event and ≥ 0.80 for percentage agreement, which is considered acceptable (Cohen, 1988). Interrater-reliability was calculated for 20% of each recording. Time-based and event-based Kappa was calculated with sequential analysis software (Bakeman & Quera, 2011). For protest time-based K = 0.83 and the K = 0.84, 9%. Seven files were consensus-coded because reliability could not be reached.

Ethics

All participants were thoroughly informed about the project and all signed a consent form. All participants in the depressed group consisted of a dichotomous split of depressed mothers from a larger sample that was found within the project. The infant’s mothers might be explained by a model which they base their behavior accumulate quickly. The infants of the diagnosed mothers might turn passive and turn to self-regulation in time (Tronick & Weinberg, 1997). Age could have played a role, since the behavior of the infant might change with the amount of PPD age (P<0.05). Infants in the present study are 16 weeks, while infants in the other studies are younger (6-11 weeks, 13 weeks, and 14.6 weeks). The differences in age are relatively small, however an infant might experience many interactions on a daily basis, making the experience on which they base their behavior accurately quickly.

Finally, the infants of depressed mothers might as a group show both a heightened and a lowered amount of protest. Adopting Beebe's mid-range model for interpretation would indicate that the different depressed samples are facing different types of regulatory variations. A heightened amount of protest would indicate that the infant is preoccupied with the interactive regulation while a lowered amount would indicate that the infant has turned to self-regulation (Beebe, Rutter, Sotir, & Kniblauch 2005).

Results

Maternal and infant characteristics

Basic characteristics of the sample are presented in Table 1. No significant differences were found in maternal age, single parent status, maternal unemployment status, maternal years of education, infant gender or infant birth weight. The two groups only differed according to depression diagnosis.

Protest results

On average, infants of non-depressed mothers showed a higher percentage of time in protest (M = 11.56, SD = 14.45) than infants of depressed mothers (M = 2.3), (SD = 4.78). This difference was highly significant (t [63.92] = 6.31, p < .001).

Discussion

Contrary to previous findings, the results of the present study showed a lowered amount of vocal protest in infants of depressed mothers. Possible interpretations will now be discussed. Figure 1 shows the results from the present and previous studies.

One possible explanation is the use of different measures. However, only across the depressed samples does the measure seem to largely impact the amount of protest. This could be explained by the presence of discordant affect in the infants of depressed mothers, which would result in different amount of protest when different modalities are measured.

Sample characteristics might have affected the results. The depressed women in the present sample can be considered low-risk (Table 1), while Field has often used particularly high-risk samples. Interactions of high-risk infant-mother dyads are quantitatively and qualitatively different (Murray & Cooper, 1997; Field, 1967). Furthermore, it has been argued that there are different types of depressed mothers characterized by different behavior patterns in mother and infant (Cohn, Malas, Tronick, Cornell, & Lytras-Ruth, 1986; Tronick & Weinberg, 1997; Field, Hernandez-Rief, & Dei, 2005). Infants of under stimulating depressed mothers were found in previous studies to turn to a protest. This could be explained by the presence of discordant affect over the infant’s mothers. This might be explained by the presence of discordant affect. The presence of discordant affect in some samples could be understood as attempts to cope with interactional disturbances by heightening or lowering the response.
