Abstract

Amount of vocal protest was measured in 4-month-old infants of depressed vs. non-depressed mothers during 10 minute face-to-face interaction. The sample consisted of a two groups of mothers with their infants: depressed (n=17) and non-depressed (n=49), in total N=66. Vocal protest was measured using PRAAT phonetic software and manual, reliable coding. Results showed that infants of depressed mothers expressed a lower amount of vocal protest compared to infants of non-depressed mothers as measured in mean percentage of time (p < .001).

Background

A significantly heightened amount of protest has previously been reported for infants of depressed mothers during face-to-face interaction (Field, Healy, Goldstein, & Guitierrez, 1994). The other studies have also reported a heightened amount of protest in infants of depressed mothers on a tendency level (Murray, For-Cowley, Hopper, & Cooper, 1996; Friedman, Beebe, Jaffe, Ross, & Trigg, 1996). Previous studies have predominantly used composite multimodal measures, which measure several modalities together (Field et al., 1990; Murray et al., 1996). However, multimodal measures may cover up so-called discordant affects (the infant is expressing converging affects through different modalities), which have been detected in infants of depressed mother (Beebe et al., 2008).

Aim

The aim of the present study was to measure amount of infant protest in infants of depressed vs. non-depressed mothers. Infants were measured using a single modality, the vocal modality, which has been found to be the main salient system through which both mother and infant communicate with each other at 4 months (Van Egeren, Barratt, & Roach, 2001).

Method

Participants

The sample consisted of 66 primiparous mothers and their infants from the urban Copenhagen area with PPD group (n=17) and non-depressed group (n=49). Inclusion criteria were: Primiparous mother, healthy infant, mother at least 18 years, living in the Copenhagen area, normal hearing and vision abilities. Exclusion criteria were: Psychosis and/or presence of co-morbid bipolar disorder and abuse of any substances.

Measures

Depression status was measured with the self-report measure Edinburgh Postnatal Depression Status (EPDS) and the standardized psychiatric interview Present State Examination (PSE). Wing, Cooper, & Sacker, 1993, which are administered by a clinical psychologist as enrollment in both groups.

Procedure

Set-up

The interaction took place according to a standardized design of mother-infant face-to-face interaction. Mother and infant were seated in front of each other at a distance of approximately 50 cm, the infant in an infant seat and the mother on a small chair. Vocal recordings were made using individually head-mounted high-quality microphones. The mother was instructed to play with their infants as she would usually do at home.

Protest results

On average, infants of non-depressed mothers showed a higher percentage of time in protest (M = 11.56, SD = 14.65) than infants of depressed mothers (M = 3.31, SD = 4.78). This difference was highly significant (F(3,92) = 3.61, p = .001).

Discussion

Contrary to previous findings, the results of the present study showed a lowered amount of vocal protest in infants of depressed mothers. Possible interpretations will now be discussed. Figure 1 shows the results from the present and previous studies.
