Bottleneck Distances and Steiner Trees in the Euclidean d-Space

Abstract

Some of the most efficient heuristics for the Euclidean Steiner minimal trees in the d-dimensional space, d ≥ 2, use Delaunay tessellations and minimum spanning trees to determine small subsets of geometrically close terminals. Their low-cost Steiner trees are determined and concatenated in a greedy fashion to obtain low cost trees spanning all terminals. The weakness of this approach is that obtained solutions are topologically related to minimum spanning trees. To obtain better solutions, bottleneck distances are utilized to determine good subsets of terminals without being constrained by the topologies of minimum spanning trees. Computational experiments show a significant solution quality improvement.

1 Introduction

Given a set of terminals N = {t₁, t₂, ..., tₙ} in the Euclidean d-dimensional space Rᵈ, d ≥ 2, the Euclidean Steiner minimal tree (ESMT) problem asks for a shortest connected network T = (V, E), where N ⊆ V. The points in S = V \ N are called Steiner points. The length |uv| of an edge (u, v) ∈ E is the Euclidean distance between u and v. The length |T| of T is the sum of the lengths of the edges in T. T must be a tree. It is called the Euclidean Steiner minimal tree and is denoted by SMT(N). Many variants with important applications in the design of transportation and communication networks and in the VLSI design have been investigated. While the ESMT problem is one of the oldest optimization problems, it remains an active research area due to its difficulty, many open questions and challenging applications. The reader is referred to [3] for the fascinating history of the ESMT problem.

The ESMT problem is NP-hard [4]. A good exact method for solving problem instances with up to 50,000 terminals in R² is available [9]. However, no analytical method can exist for d ≥ 3 [1]. Furthermore, no numerical approximation seems to be able to solve instances with more than 15-20 terminals [6]. It is therefore essential to develop good quality heuristics for d ≥ 3. Several heuristics have been proposed in the literature [15, 7, 10]. In particular, the heuristic suggested in [10] builds on a R²-heuristic [13]. Both use Delaunay tessellations and Minimum spanning trees and are therefore referred to as DM-heuristics.

SMT(N) must have n − 2 Steiner points, each incident with 3 edges [8]. Terminals must be incident with exactly 1 edge (possible of zero-length). Non-zero-length edges must meet at Steiner points at angles that are at least 120°. If a pair of Steiner points sᵢ and sⱼ is connected by a zero-length edge, then sᵢ or sⱼ is connected via a zero-length edge to a terminal and the three non-zero-length edges incident with sᵢ and sⱼ must make 120° with each other. Any geometric network ST(N) satisfying the above degree and angle conditions is called a Steiner tree. The underlying undirected graph (where the coordinates of Steiner points are immaterial) is called a Steiner topology of N. If ST(N) has no zero-length edges, then it is called a full Steiner tree. Every Steiner tree ST(N) can be decomposed into one or more full Steiner subtrees whose degree one points are either terminals or Steiner points overlapping with terminals.

A reasonable approach to find a good suboptimal solution to the ESMT problem is therefore to identify few subsets N₁, N₂, ..., Nᵣ, and their low cost Steiner trees ST(N₁), ST(N₂), ..., ST(Nᵣ), such that a union ST(N) of some of them will be a good approximation of SMT(N).

The Delaunay tessellation of N in Rᵈ is denoted by DT(N) [2]. It is well-known that a minimum spanning tree of N, denoted by MST(N), is a subgraph of DT(N). A face σ of DT(N) is covered if the subgraph of MST(N) induced by the corners of σ is a tree.

Let Nσ ⊆ N denote the corners of a face σ of DT(N). Let ST(Nσ) denote a Steiner tree spanning Nσ. Let F be a forest whose vertices form a superset of N. Suppose that the terminals of N are in different subtrees of F. The concatenation F ⊕ ST(Nσ) of F with ST(Nσ) is a forest obtained by adding to F all Steiner points and all edges of ST(Nσ).

Let T = MST(N). The contraction T ⊕ Nσ of T by Nσ is obtained by replacing the vertices in Nσ by a single vertex tσ. Cycles in T ⊕ Nσ are destroyed by removing their longest edges.

The DM-heuristic constructs DT(N) and MST(N) in the preprocessing phase. For corners Nσ of every covered face σ of DT(N), a low cost Steiner tree ST(Nσ) is determined [10]. If full, it is stored in a priority queue Q ordered by non-decreasing Steiner

This is an extended abstract of a presentation given at EuroCG 2016. It has been made public for the benefit of the community and should be considered a preprint rather than a formally reviewed paper. Thus, this work is expected to appear in a conference with formal proceedings and/or in a journal.
ratios $\rho(\text{ST}(N_\sigma)) = |\text{ST}(N_\sigma)| / |\text{MST}(N_\sigma)|$. Greedy concatenation, starting with the forest $F$ of isolated terminals in $N$, is then used to form $\text{ST}(N)$.

The weakness of the DM-heuristic is that it relies on covered faces of DT($N$). The Steiner topology of $\text{ST}(N)$ is therefore dictated by the topology of $T$. This is a good strategy in many cases but there are also cases where this will exclude good solutions. Consider for example the two Steiner trees in Fig. 1. Only covered faces of DT($N$) are considered in $T_{DM}$. By considering some uncovered faces (shaded), a better Steiner tree $T_{DB}$ can be obtained.

We wish to detect useful uncovered faces and include them into the greedy concatenation. However, some uncovered faces of DT($N$) may be harmful in the greedy concatenation even though they seem to be useful locally. As illustrated in Fig. 2, use of the uncovered face $\sigma$ of DT($N$) in $\mathbb{R}^2$ with the set of corners $N_\sigma = \{t_i, t_j, t_k\}$ will lead to a Steiner tree ST($N$) longer than $T$ while the ratio $\rho(\text{ST}(N_\sigma))$ is lowest among all faces of DT($N$).

Figure 2: $\rho(\text{ST}(N_\sigma))$ for $N_\sigma = \{t_i, t_j, t_k\}$ is low but the inclusion of ST($N_\sigma$) increases its length beyond $|T|$.

2 DB-Heuristic in $\mathbb{R}^d$

The bottleneck distance $|t_i t_j|_T$ between two terminals $t_i, t_j \in N$ is the length of the longest edge on the path from $t_i$ to $t_j$ in $T = \text{MST}(N)$. Note that $|t_i t_j|_T = |t_i t_j|$ if $(t_i, t_j) \in T$.

The bottleneck minimum spanning tree $B_T(N_\sigma)$ of a set of points $N_\sigma \subseteq N$ is defined as the minimum spanning tree of the complete graph with $N_\sigma$ as its vertices and with $|t_i t_j|_T$ being the cost of an edge $(t_i, t_j), t_i, t_j \in N_\sigma$. If $N_\sigma$ is covered by $T$, then $|B_T(N_\sigma)| = |\text{MST}(N_\sigma)|$.

Consider a Steiner tree ST($N_\sigma$) spanning $N_\sigma \subseteq N$. Let the bottleneck Steiner ratio $\beta_T(\text{ST}(N_\sigma)) = |\text{ST}(N_\sigma)| / |B_T(N_\sigma)|$ if $N_\sigma$ is covered by $T$, then $\beta_T(\text{ST}(N_\sigma)) = \rho(\text{ST}(N_\sigma))$.

The DB-heuristic constructs the Delaunay tesselation DT($N$) and uses $T$ to determine bottleneck distances. For corners $N_\sigma$ of each $k$-face $\sigma$ of DT($N$), $2 \leq k \leq d + 1$, a low cost Steiner tree ST($N_\sigma$) is determined using a heuristic [10]. Each full ST($N_\sigma$) is stored in a priority queue $Q_B$ ordered by non-decreasing bottleneck Steiner ratios. If $\sigma$ is a 1-face, then ST($N_\sigma$) is the edge connecting the two corners of $\sigma$. Such ST($N_\sigma$) is added to $Q_B$ only if it is an edge in $T$.

Let $F$ be the forest of isolated terminals from $N$. A greedy concatenation is then applied repeatedly until $F$ becomes a tree. Let ST($N_\sigma$) be a Steiner tree with currently smallest bottleneck Steiner ratio in $Q_B$. If any pair of terminals in $N_\sigma$ is connected in $F$, ST($N_\sigma$) is discarded. Otherwise, $F = F \oplus \text{ST}(N_\sigma)$ and $T = T \cup N_\sigma$, see Fig. 3. Such contraction of $T$ may reduce bottleneck distances between up to $O(n^2)$ pairs of terminals. Hence, bottleneck Steiner ratios of some Steiner trees still in $Q_B$ need to be updated, preferably in a lazy fashion, see Section 3.

Figure 3: The insertion of $\text{ST}(N_\sigma)$, $N_\sigma = \{t_i, t_j, t_k\}$

3 Contractions and Bottleneck Distances

As face-spanning Steiner trees are added to $F$, their corners are contracted in the current minimum spanning tree $T$. Contractions will reduce bottleneck distances between some pairs of terminals. As a consequence, bottleneck Steiner ratios of face-spanning Steiner trees still in $Q_B$ will increase. A face-spanning Steiner tree subsequently extracted from $Q_B$ will not necessarily have the smallest bottleneck Steiner ratio unless $Q_B$ has been rearranged or appropriate lazy updating is carried out.

Steiner trees of faces of DT($N$) are extracted from $Q_B$ one by one. A face $\sigma$ is discarded if some of its
corners are already connected in F. The bottleneck Steiner ratio \( \beta_T(ST(N_\sigma)) \) of the extracted Steiner tree \( ST(N_\sigma) \) may have changed since the last time \( ST(N_\sigma) \) was pushed onto \( Q_B \). Hence, \( \beta_T(ST(N_\sigma)) \) has to be recomputed. If it increased, \( ST(N_\sigma) \) is pushed back onto \( Q_B \) (with the new bottleneck Steiner ratio). If not, \( ST(N_\sigma) \) is used to update \( F \) and to contract \( T \).

A modified version of a dynamic rooted tree [12] to maintain a changing minimum spanning tree \( T \) (caused by contractions) and to answer bottleneck distance queries has been used. When using balanced binary trees to implement dynamic rooted trees, a bottleneck distance query takes \( O((\log n)^2) \) amortized time. Since only faces of \( DT(N) \) are considered, a contraction takes \( O((d \log n)^2) \) time.

4 Computational results

The DB-heuristic was compared with the DM-heuristic. Both Steiner ratios and CPU times were examined. To get reliable comparisons, they were averaged over several runs. Furthermore, the results in \( \mathcal{R}^2 \) were compared with the results achieved by the exact GeoSteiner algorithm [9].

The DM- and DB-heuristics were implemented in C++ \(^1 \) and run on a Lenovo ThinkPad S540 with a 2 GHz Intel Core i7-4510U processor and 8 GB RAM. Both heuristics were tested on randomly generated problem instances in \( \mathcal{R}^d \), \( d = 2, 3, \ldots, 6 \), as well as on library problem instances. Randomly generated instances were points uniformly distributed in \( \mathcal{R}^d \)-hypercubes.

The library problem instances consisted of the benchmark instances from the 11-th DIMACS Challenge [5]. For comparing the DB-heuristic with the GeoSteiner algorithm, ESTEIN instances in \( \mathcal{R}^2 \) were used [5].

The new DB-heuristic outperforms the DM-heuristic by 0.2–0.3% for \( d = 2 \), 0.4–0.5% for \( d = 3 \), 0.6–0.7% for \( d = 4 \), 0.7–0.8% for \( d = 5 \) and 0.8–0.9% for \( d = 6 \). This is a significant improvement for the ESMT problem as will be seen below, when comparing \( \mathcal{R}^2 \)-results to the optimal solutions obtained by the exact GeoSteiner algorithm [9].

CPU times for the DM- and DB-heuristics for \( d = 2, 3, \ldots, 6 \), are shown in Fig. 4. It can be seen that the improved quality comes at a cost for \( d \geq 4 \). This is due to the fact that the DB-heuristic constructs low cost Steiner trees for all \( O(n^{d/2}) \) faces of \( DT(N) \) [11] while the DM-heuristic does it for covered faces only.

Fig. 5 shows how DB-, DM-heuristic and GeoSteiner (GS) performed on ESTEIN instances in \( \mathcal{R}^2 \). Steiner ratios and CPU times averaged over all 15 ESTEIN instances of the given size, except for

\( n = 10.000 \) which has only one instance. It can be seen that the DB-heuristic produces better solutions than the DM-heuristic without any significant increase of the CPU time. It is also worth noticing that the DB-heuristic gets very close to the optimal solutions. This may indicate that the DB-heuristic also produces high quality solutions when \( d > 2 \), where optimal solutions are only known for instances with at most 20 terminals.

The results for ESTEIN instances in \( \mathcal{R}^3 \) are presented in Fig. 6. The green plot for \( n = 10 \) is the average ratio and CPU time of the exact solutions [14]. Once again, the DB-heuristic outperforms the DM-heuristic when comparing the quality of solutions. However, the running times are now up to four times worse.

The DB-heuristic starts to struggle when \( d \geq 4 \).
This is caused by the number of faces of DT(N) for which low cost Steiner trees must be determined. The DB-heuristic was therefore modified to consider only faces with less than $k$ terminals, for $k = 3, 4, ..., d + 1$.

Fig. 7 shows the performance of this modified DB$_k$-heuristic for $k = 3, 4, ..., 7$, on a set with 100 terminals in $\mathbb{R}^6$. Note that DB$_7 = DB$.

As expected, the DB$_k$-heuristic runs much faster when larger faces of DT(N) are disregarded. Already the DB$_4$-heuristic seems to be a reasonable alternative since solutions obtained by DB$_k$-heuristic, $5 \leq k \leq 7$ are not significantly better.

5 Summary and conclusion

Computational results show a significant improvement in the quality of the Steiner trees produced by the DB-heuristic where the topologies of the solutions are no longer constrained by minimum spanning trees. Its CPU times are comparable to the CPU times of the DM-heuristic in $\mathbb{R}^d$, $d = 2, 3$. It runs slower for $d \geq 4$. However, CPU times can be significantly improved by skipping larger faces of DT(N). This results in only small decrease of quality of solutions obtained.
