Centrality dependence of the nuclear modification factor of charged pions, kaons, and protons in Pb-Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV

J. Adam et al.*
(ALICE Collaboration)

(Received 7 July 2015; revised manuscript received 9 November 2015; published 25 March 2016)

Transverse momentum ($p_T$) spectra of pions, kaons, and protons up to $p_T = 20$ GeV/$c$ have been measured in Pb-Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV using the ALICE detector for six different centrality classes covering 0%–80%. The proton-to-pion and the kaon-to-pion ratios both show a distinct peak at $p_T \approx 3$ GeV/$c$ in central Pb-Pb collisions that decreases for more peripheral collisions. For $p_T > 10$ GeV/$c$, the nuclear modification factor is found to be the same for all three particle species in each centrality interval within systematic uncertainties of 10%–20%. This suggests there is no direct interplay between the energy loss in the medium and the particle species composition in the hard core of the quenched jet. For $p_T < 10$ GeV/$c$, the data provide important constraints for models aimed at describing the transition from soft to hard physics.

I. INTRODUCTION

In ultrarelativistic heavy-ion collisions, a strongly interacting deconfined medium of quarks and gluons is created. Experimental evidence for this state of matter has been found at both the Relativistic Heavy Ion Collider (RHIC) [1–4] and the CERN Large Hadron Collider (LHC) [5–9]. Transverse momentum ($p_T$) spectra probe many different properties of this medium. At low $p_T (\lesssim 2$ GeV/$c$) the spectra provide information on bulk production, while at high $p_T (\gtrsim 10$ GeV/$c$) transport properties of the medium can be studied via jet quenching [10–12]. The microscopic QCD processes are different at low and high $p_T$, and it is an open question if additional physics processes occur in the intermediate $p_T$ region ($2 \lesssim p_T \lesssim 10$ GeV/$c$). In this paper, the centrality evolution of the transverse momentum spectra of pions, kaons, and protons as a function of $p_T$ for Pb-Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV is presented. The focus is on intermediate and high $p_T$, where these measurements allow comparison between baryons and mesons, strange and nonstrange particles, and the search for particle mass-dependent effects.

For inclusive charged-particle $p_T$ spectra, jet quenching leads to a suppression of high-$p_T$ particle production at the RHIC [13–15] and over an extended $p_T$ range, up to 100 GeV/$c$, at the LHC [6,16–18]. The microscopic mechanism of jet quenching is not completely understood, and one of the main goals of the experimental programs at the RHIC and the LHC is to identify additional signatures associated with the jet quenching to constrain theoretical modeling. Particle identification (PID) is of fundamental interest because, owing to the color Casimir factor, gluons interact two times stronger with the medium than quarks [19,20] and it is known from $e^+e^-$ studies of three-jet events that gluons are more likely to fragment to leading baryons than quarks are [21]. In addition, some models for jet quenching predict large particle-species-dependent effects [22–24]. Measurements at the RHIC, in particular for baryons, have so far been inconclusive owing to the limited $p_T$ range and the large systematic and statistical uncertainties [25–27].

In the intermediate transverse momentum regime, the baryon-to-meson ratios, e.g., the proton yield divided by the pion yield, measured by experiments at the RHIC revealed a, so far, not well understood enhancement [28–30]. This so-called “baryon anomaly” could indicate the presence of new hadronization mechanisms such as parton recombination [31–33] that could be significantly enhanced and/or extended out to higher $p_T$ at the LHC owing to larger minijet production [34]. In recombination models, the enhancement at intermediate $p_T$ is an effect of the coalescence of lower $p_T$ quarklike particles that leads to a larger production of baryons than mesons. In a model without new intermediate $p_T$ physics, the rise of the baryon-to-meson ratio is attributable to hydrodynamics and the decrease is solely a consequence of the growing importance of fragmentation.

In a recent letter [35] ALICE reported the charged pions, kaons, and proton $p_T$ spectra for $pp$ and the most central and most peripheral Pb-Pb collisions. The main observation was that, within statistical and systematic uncertainties, the nuclear modification factor is the same for $p_T > 10$ GeV/$c$ for all three particle species. This suggests that there are no significant particle-species-dependent effects related to the energy loss. In this paper, the analysis used to obtain the measurements at high $p_T$ is presented in full detail, and the results for all centrality classes are included. Recent measurements at low and intermediate $p_T$ of identified particle production and correlations in $p$-Pb collisions have revealed phenomena typically associated with fluidlike behavior in heavy-ion collisions [36–38]. This raises questions of whether hydrodynamics and/or recombination can also be applied to describe these small systems [39–41]. The centrality evolution studies for Pb-Pb collisions can therefore also be seen as a possible experimental interconnection between the smallest and the largest QCD bulk systems.

The outline of this paper is as follows. In Sec. II, the data analysis is described. The method using the energy loss in
the TPC for particle identification is laid out first and then the procedure using the Cherenkov angle measured by the high-momentum particle identification detector (HMPID) is presented. In Sec. III, the final spectra are presented, and the particle ratios and nuclear modification factors are discussed and compared with theoretical calculations and results from previous experiments at lower center-of-mass energies.

II. DATA ANALYSIS

The results reported in this paper have been obtained with the central barrel of the ALICE detector, which has full azimuthal coverage around midrapidity, \(|\eta| < 0.8\) [42]. Different particle identification (PID) devices are used for the identification of \(\pi^\pm\), \(K^\pm\), and \(p(\bar{p})\) (see Table IV for exact \(p_T\) ranges). Ordering by \(p_T\), from lowest to highest, the results are obtained using the specific energy loss, \(dE/dx\), in the silicon inner tracking system (ITS), the \(dE/dx\) in the time projection chamber (TPC), the time of flight measured by the time-of-flight (TOF) detector, the Cherenkov angle measured by the HMPID, and the TPC \(dE/dx\) in the relativistic rise region. The general performance of these devices is reported in Ref. [43]. Detailed description of the lower \(p_T\) analyses and the resulting \(\pi^\pm\), \(K^\pm\), and \(p(\bar{p})\) \(p_T\) spectra in Pb-Pb collisions are already published [44]. In this section, the method used to extract these \(p_T\) spectra in the HMPID and the TPC \(dE/dx\) relativistic rise analysis is described in detail.

Owing to the limited acceptance of the HMPID, the analysis has been performed with the larger 2011 data set where a centrality trigger was used, restricting the HMPID results to 0%-50% central Pb-Pb collisions.

A. TPC \(dE/dx\) relativistic rise analysis

The relativistic rise of the \(dE/dx\) in the TPC, where the average energy loss increases as \(\ln \beta \gamma (3 < \beta \gamma < 1000)\), allows ALICE to extend the PID of \(\pi^\pm\), \(K^\pm\), and \(p(\bar{p})\) up to \(p_T = 20\) GeV/c. This section focuses on details of this analysis.

1. Event and track selection

The event and track selection follows closely that of the inclusive charged particle analysis [16]. The same spectrum normalization is adopted so that the systematic uncertainties related to event and track selection are common, allowing a precise comparison between the nuclear modification factors for inclusive and identified charged particles. The analysis with PID described here has additional systematic uncertainties related to the particle identification that we describe in Sec. II A 9.

A total of \(11 \times 10^6\) Pb-Pb collision events recorded in 2010 are used in this analysis. The online (offline) trigger for minimum bias interactions in Pb-Pb collisions requires signals in two (three) of the three following detector elements: the silicon pixel detector (SPD) layers of the ITS and the two forward scintillators (V0) located on opposite sides of the interaction point. The centrality is determined from the measured amplitude in the V0 detector [45].

Primary tracks are reconstructed in the ALICE TPC [46] from clusters in up to 159 pad rows, where each cluster consists of a group of cells covering a few neighboring pads and time bins. The tracks used in the analysis are restricted to \(|\eta| < 0.8\) to be fully contained in the TPC active volume. Furthermore, tracks are required to have at least one hit in one of the two innermost SPD layers of the ITS, and the distance of closest approach to the primary vertex is required to be less than 2 cm along the beam axis and less than 7 standard deviations in the transverse plane (=350 \(\mu m\) for tracks with \(p_T = 2\) GeV/c, decreasing slightly with \(p_T\)). The resulting relative \(p_T\) resolution for these tracks is better than 5% at \(p_T = 20\) GeV/c [16]. The \(p_T\) spectra have been corrected for this resolution using an unfolding procedure for \(p_T > 10\) GeV/c [16,47]. This correction is smaller than 2% at \(p_T = 20\) GeV/c.

2. Particle identification at large transverse momentum

Figure 1 shows the \(dE/dx\) as a function of momentum \(p\) in 0%-5% and 60%-80% central Pb-Pb collisions. It is evident

![Graphs showing dE/dx as a function of momentum p at midrapidity |η| < 0.2 for 0%-5% (left) and 60%-80% (right) Pb-Pb collisions. In each momentum bin, the dE/dx spectra have been normalized to have unit integrals and only bins with more than 0.1% of the counts are shown (making electrons not visible in this plot except at very low momentum). The curves show the final (dE/dx) responses for pions, kaons, and protons.](https://example.com/graphs.png)
that particle identification in the relativistic rise region requires precise knowledge of the $\langle dE/dx \rangle$ response and resolution $\sigma$. To quantify this, and to motivate the detailed studies in the following, the final response functions are used to estimate the separation power, where, for example, the charged pion-to-kaon separation in number of standard deviations, $S_\sigma$, is

$$S_\sigma = \frac{\langle dE/dx \rangle_\pi^+ - \langle dE/dx \rangle_\pi^-}{0.5(\sigma_{\pi^+} + \sigma_{\pi^-})},$$

(1)

that is, the absolute $\langle dE/dx \rangle$ difference normalized to the arithmetic average of the resolutions. Figure 2 shows that the separation power between particle species is only a few standard deviations, making PID very challenging, requiring optimization of the $dE/dx$ signal itself and the use of external PID constraints to calibrate the response. In the following, these analysis aspects are covered in detail.

3. The $dE/dx$ calibration

The $dE/dx$ is obtained as a truncated mean, where the average is performed considering only the 60% lowest cluster charge values to remove the tail of the Landau-like cluster charge distribution. It is customary to use the notation $dE/dx$ and talk about the Bethe-Bloch curve, even if the $dE/dx$ used in the analysis is only the truncated mean and does not contain energy losses deposited as sub-ionization-threshold excitations or the full ionization from $\delta$ electrons, discussed in detail in Ref. [48]. While the Bethe-Bloch specific energy loss depends only on $\beta\gamma = p/m$, the one obtained from the detected truncated mean also depends on other parameters such as the actual cluster sample length, i.e., the pad length and/or track inclination over the pad. In the following, we refer to the relationship between the two types of specific energy losses as the transfer function and it is this relationship that is optimized in the $dE/dx$ calibration and used also as input for the analysis strategy discussed later.

Each of the up to 159 clusters used to reconstruct a track contains information on the ionization energy loss in the TPC. To equalize the gain, each individual readout channel has been calibrated using ionization clusters produced by the decay of radioactive krypton, $^{86}\text{Kr}$, released into the TPC gas [46]. In $pp$ collisions the cluster integrated charge is used for calculating the $dE/dx$. The integrated charge is corrected for the tails of the charge distribution that are below the readout threshold. Owing to the large probability for overlapping clusters in Pb-Pb collisions, the maximum charge in the cluster is used to calculate the $dE/dx$ in this case. The maximum charge is the largest charge in a cluster cell (pad and time bin). The maximum charge has to be corrected for the drift-length-dependent reduction owing to diffusion and the
dependence on the relative pad position of the induced signal (the measured maximum charge is largest if the cluster center is also the pad center and smallest if it is between two pads).

The performance and stability of the $dE/dx$ transfer function, with respect to gain variations, is improved in the following two ways. Reconstructed space points where the charge is deposited on a single pad, that are not used for track fitting, are included in the $dE/dx$ calculation. An attempt is made to identify clusters below the readout threshold. If a row has no cluster assigned to the track but clusters were assigned in both neighboring rows, it is assumed that the cluster charge was below the readout threshold and a virtual cluster is assigned with charge corresponding to the lowest reconstructed charge cluster on the track. This virtual cluster is then included in the calculation of the truncated mean. This is similar to the strategy adopted by ALEPH, but without changing the truncation range [49].

The $\eta$ dependence of the $dE/dx$ is sensitive to corrections for the track length and the diffusion. There is also a small correction for the direct drift-length-dependent signal attenuation, owing to absorption, of ionization electrons by oxygen [46]. At $\eta = 0$ the ionization electrons drift the full 250 cm to the readout chambers and, as a result, the signal is spread out, owing to diffusion, making threshold effects more prominent than for tracks with $\eta = 0.8$. At the same time, the sampled track length is longer for the track with $\eta = 0.8$ than that with $\eta = 0$. The $dE/dx$ calibration is validated using pions in the minimum ionizing particle (MIP) regime and electrons in the Fermi plateau region. A clean sample of MIP pions is selected via tracks with momenta $0.4 < p < 0.6$ GeV/c and energy loss $0.8 < (dE/dx)/(dE/dx)_{\text{MIP}} < 1.2$. A clean electron sample is obtained in the same momentum range via centrality-dependent $dE/dx$ cuts (as $S_\eta$ depends on centrality) and by rejecting kaons using time-of-flight (TOF) information: $0.9 < \beta_{\text{TOF}} < 1.1$. For both samples it is found that the $\eta$ dependence of the $dE/dx$ is negligible. We note that one expects these two classes of tracks to have different sensitivity to threshold corrections. The result of the validation test for $pp$ collisions is shown in Fig. 3, which displays the $(dE/dx)$ response as a function of $\eta$ for electrons (top panel) and pions (middle panel).

4. Division into homogenous samples

From studies of the transfer function, one expects a significant track-length dependence. For the “stiff” high-$p_T$ tracks used in this analysis, the track length in the transverse bending plane is rather similar, but there is a significant $\eta$ dependence and the effect of this on the $dE/dx$ resolution is visible in Fig. 3 for the pion MIPs. This motivates performing the analysis in $|\eta|$ intervals $-0.2 \leq |\eta| < 0.4$, $0.4 \leq |\eta| < 0.6$, and $0.6 \leq |\eta| < 0.8$—and then combining the results.

Furthermore, tracks close to and/or crossing the TPC sector boundaries have significantly fewer clusters assigned. Because the analyzed tracks are “stiff,” those tracks close to the sector boundaries can be easily rejected using a geometric cut in the azimuthal track angle $\phi$, which excludes approximately 10% of the tracks for $p_T > 6$ GeV/c. Figure 4 shows the effect of the geometric cut on the distribution of the number of clusters per track. The cases before and after the $\phi$ cut are shown for $pp$ (top panel) and central Pb-Pb (bottom panel) collisions. The large difference between the distributions for $pp$ and central Pb-Pb is an occupancy effect and essentially independent of $p_T$. The cut significantly improves the $dE/dx$ performance by rejecting tracks with less information (fewer clusters) in regions where the calibration is more sensitive to complex edge behaviors that can have larger effects on stiff tracks. This also simplifies the analysis because in each $|\eta|$ interval, a single resolution parameter is sufficient to describe individual particles species (e.g., all pions) in a given momentum bin.

5. Obtaining the high-$p_T$ yields

Because, as already mentioned, the event and track selection scheme is identical to the one used for the inclusive charged-particle spectra [16] and each charged track has an associated TPC $dE/dx$ measurement, the charged pion, kaon, and (anti)proton yields measured in this analysis are normalized...
yields show less than 2% systematic deviations. From studies comparing test beam data results with the ALICE specific MC implementation of the energy loss in the TPC, the MC is known to be precise and to take into account all important detector effects [50], with the limit that the test beam data was recorded under controlled conditions (fixed track topology and large gas gain) and that ion tail effects are not included in the MC simulations.

The first step of the analysis is to extract the response parametrizations used to constrain the fits. The Bethe-Bloch curve is parametrized as

$$\left\langle \frac{dE}{dx} \right\rangle = a \left[ 1 + \left( \beta \gamma \right)^2 \right] + b \ln \left[ \frac{1 + \beta \gamma}{1 + d'(1 + \beta \gamma)^2} \right],$$

where $a$, $b$, $c$, $d$, and $e$ are free parameters (the variable $d'$ is used to simplify the expression and is defined as $d' = \exp[(a - d)/b]$, where $d$ is the $\langle dE/dx \rangle$ in the Fermi plateau regime, $\beta \gamma > 1000$).

For $d' \ll 1$, as is the case here, the parametrization has a simple behavior in different regions of $\beta \gamma$. For small $\beta \gamma$, $\beta \gamma \ll 3-4$, $\langle dE/dx \rangle \approx a(\beta \gamma)^{e}$, while on the logarithmic rise, $\langle dE/dx \rangle \approx a + b \ln(1 + \beta \gamma)$. The parametrization has been motivated by demanding this behavior in the discussed $\beta \gamma$ limits, while at the same time requiring that each parameter has a clear meaning. It uses $1 + \beta \gamma$ to ensure that the logarithmic term is always positive.

The relative resolution, $\sigma/(dE/dx)$, as a function of $\langle dE/dx \rangle$ is parametrized with a second-degree polynomial, which was found to describe the data well:

$$\frac{\sigma}{\langle dE/dx \rangle} = a_0 + a_1 \langle dE/dx \rangle + a_2 \langle dE/dx \rangle^2.$$  \hfill (3)

The TPC response (Bethe-Bloch and resolution curves) is determined for each $\eta$ region. Owing to the deterioration of the TPC $dE/dx$ performance with increasing multiplicity, the curves differ significantly and have to be extracted separately for $pp$ and each Pb-Pb centrality class.

The parameters $a$, $b$, $d$, and $e$ are well determined using external PID information. Secondary pion (proton) tracks identified via the reconstruction of the weak decay topology of $K^0_S$ ($\Lambda$) and data samples with TOF enhanced ($\beta_{TOF} > 1$) primary pions are used. The $V^0$ selection used in this analysis is similar to the one used in the dedicated analysis [51]. To verify that the $dE/dx$ response is Gaussian, narrow invariant-mass cuts were applied to $pp$ data where the $V^0$ reconstruction is cleanest. Figure 6 shows single Gaussian fits to the pion and proton peaks for such data and we note that the reduced $\chi^2$ value is in the expected range for a valid fit model. In the following, 10 MeV/c$^2$ wide invariant-mass cuts around the peaks were used to select signal and reject background as a compromise between statistics and purity. Using this information, the Bethe-Bloch function is constrained in the $\beta \gamma$ interval of 3–60. Figure 7 shows examples of the TPC $dE/dx$ spectra for these samples in the momentum ($\eta$) range: 5–7 GeV/c ($0.6 < |\eta| < 0.8$) for the most central and most peripheral Pb-Pb collisions analyzed. In this case, the proton.

---

1The $\varphi$ cut described in Sec. II A 4 was not applied in the inclusive charged-particle analysis, but as this cut is a geometric cut it is independent of particle species type and therefore does not affect this normalization.
FIG. 5. Four-Gaussian fits (line) to the \(dE/dx\) spectra (markers) for tracks having momentum in the range 3.4–3.6 GeV/c (top) and 8.0–9.0 GeV/c (bottom) with \(|\eta| < 0.2\). In each panel, the signals of pions (rightmost Gaussian), kaons, and protons (leftmost Gaussian) are shown as red, green, and blue hatched areas, respectively. The contribution of electrons is small (<1%) and therefore not visible in the figure. Results for all six Pb-Pb centrality classes are presented. The \(dE/dx\) spectra have all been normalized to have unit integrals.

candidate samples from the \(\Lambda\) decay are not pure samples and have some contamination of pions because the invariant mass peak region still contains considerable combinatorial background. This contamination is seen in the asymmetry towards the higher value of \(dE/dx\) in the proton sample. In the case of the pion samples from the \(K_S^0\) decay, proton contamination creates the asymmetry towards the lower value of \(dE/dx\) in the spectra. Hence, in these cases, to obtain the mean \(dE/dx\) and resolution for each particle species, the asymmetric tail of the Gaussians were not considered.
because in this region
as the external PID data.
the Fermi plateau is fixed using electron-positron pairs from photon conversions (a photon conversion is reconstructed similar to a $V^0$ decay and identified from the low invariant mass). The same information is used to measure the $dE/dx$ resolution as a function of $<dE/dx>$. The relative resolution around the MIP\textsuperscript{2} is $\approx 5.5\% - 7.5\%$ and improves with increasing $<dE/dx>$ (primary ionization) in the relativistic rise region to $\approx 4.5\% - 5.5\%$. These data samples are henceforth referred to as the external PID data.

In the relativistic rise region, the analysis is very stable because in this region $<dE/dx> \approx a + b \ln \beta \gamma$, so the $dE/dx$ separation between particle species, e.g., protons and pions, is constant: $<dE/dx>_p - <dE/dx>_{\pi} \approx a + b \ln (p/m_p) - [a + b \ln (\rho/m_\pi)] \approx b \ln (m_\pi/m_p)$. So as long as all particle species are in this $\beta \gamma$ regime a simple extrapolation can be applied. For $\beta \gamma \gtrsim 100$ the pions ($p \gtrsim 14$ GeV/c) start to approach the Fermi plateau region and the $dE/dx$ dependence on $\beta \gamma$ is more complex. To address this, a two-dimensional fit to the $dE/dx$ vs $p$ distribution is performed. All the parameters of the resolution function and the parameters $a$, $b$, $d$, and $e$ of Eq. (2) are fixed. The parameter $c$ and the yields of $\pi^+ + \pi^-$, $K^+ + K^-$, and $p + \bar{p}$ in different momentum intervals are free parameters. This fit method works fine if the corrections to the logarithmic rise, owing to the transition to the plateau, are small, which restricts the current analysis to $p_T < 20$ GeV/c. With higher statistics and the use of cosmic muons as additional constraints, we expect to be able to extend the method up to 50 GeV/c.

There is a final subtle point that should be mentioned here. The systematic uncertainty on the yields from the $dE/dx$ method alone is rather large for particles with ionization

\textsuperscript{2}The resolution depends on centrality and track length and is worse in central events and for smaller $|\eta|$. 

FIG. 6. $dE/dx$ spectra for secondary pions (top) and protons (bottom) identified via the reconstruction of the weak decay topology of $K_S^0$ and $\Lambda$, respectively. A narrow invariant-mass cut reducing statistics was applied to select clean samples (but the pion sample still contains a small visible proton background). The curves are single Gaussian fits to the data and the reduced $\chi^2$ is calculated in the range indicated by the fit curves only.

The systematic uncertainty on the yields from the $dE/dx$ method alone is rather large for particles with ionization

FIG. 7. $dE/dx$ spectra for secondary pions (open triangles) and protons (solid circles) identified via the reconstruction of the weak decay topology of $K_S^0$ and $\Lambda$, respectively. The spectra have been normalized to have the same integrals. The spectrum for primary pions (solid triangles) is obtained by requiring $p_{TOF} > 1$. Results for peripheral (top) and central (bottom) Pb-Pb collisions are shown. The tracks were chosen in the momentum (pseudorapidity) interval $5 < p < 7$ GeV/c ($0.6 \leq |\eta| < 0.8$). Note that most spectra also contain a well-understood background.
The effect of this refit is largest in central collisions at low 
with the neutral kaon yield (the pion and proton yields are free). 
while the other parameters, which mainly affects the proton 
(60%–80%) collision centrality.

Through Eqs. (5) and (4). 

The two-dimensional fit is applied again, but the parameter 
e affects the neutral kaon yields 
measurements, as this will introduce a direct bias in the final 
curves obtained as described in the text. Results are shown for 
pp collisions.

Figure 8 shows the final parametrizations of the Bethe-Bloch 
and the most central 
, are constrained and the 
distributions for pions, kaons, protons, and electrons. For each 
six centrality classes and 
were found to be comparable at the 5% level or better for all 
negative pions, kaons, and protons. Positive and negative yields 
by less than 1% in the full 
for central and peripheral Pb-Pb collisions and pp collisions. 
Results are given as the range found for the four |η| intervals.

7. Extraction of the particle fractions

All the following results are for the sum of positive and 
negative pions, kaons, and protons. Positive and negative yields 
were found to be comparable at the 5% level or better for all 
six centrality classes and pp collisions.

Having determined the Bethe-Bloch and resolution curves as 
described in the previous section, it is now straightforward to 
fit the dE/dx spectra using the sum of four Gaussian 
distributions for pions, kaons, protons, and electrons. For each 
momentum interval, the (dE/dx) position and width of each 
Gaussian are fixed. Figure 5 shows examples of these fits for 
the momentum intervals 3.4–3.6 GeV/c and 8–9 GeV/c. The 
electrons are hardly visible in any of the fits as the yield is 
below 1% of the total. For pT > 10 GeV/c, it is no longer possible 
to separate electrons from pions, and the relative fraction of 
electrons is assumed to remain constant above this pT. There 
is a small contamination of primary muons in the pions owing 
to the similar mass (and therefore similar ⟨dE/dx⟩). High-pT 
muons are predominantly the result of semileptonic decays of 
hadrons containing heavy quarks and for those decays one 
expects muon and electron branching ratios to be similar, so the 
electron yield (fraction) is subtracted from the pions to correct 
for the muon contamination. This correction changes the pion 
yield by less than 1% in the full pT range, in agreement with 
MC simulations based on the PYTHIA generator [52]. Because 
this dE/dx analysis is not optimized for electrons and the 
contamination is extrapolated to high pT, half of the correction 
is assigned as a systematic uncertainty. The contamination of 
(anti)deuterons in the (anti)proton sample is negligible (<1%).

---

3The assumption is that the invariant pT spectra are the same. 
The charged kaon fraction (fK+) is obtained working backwards 
through Eqs. (5) and (4).
The particle fractions, i.e., the contribution of charged pions ($f'_{\pi^+\pi^-}$), kaons ($f'_{K^+K^-}$), and (anti)protons ($f'_{p+\bar{p}}$) to the yield of inclusive charged particles, obtained as a function of momentum, are plotted in Fig. 9 (top) as a function of centrality for the two extreme $|\eta|$ intervals. One observes a significant $\eta$ dependence of pion and proton fractions for $p < 10$ GeV/c. The extracted fractions as a function of transverse momentum are obtained bin by bin using a weighting procedure

$$f_{\text{id}}(\langle p_T \rangle_i) = \sum_j f'_{\text{id}}(\langle p \rangle_j)R(\langle p \rangle_i,\langle p_T \rangle_j),$$

where $f_{\text{id}}$ ($f'_{\text{id}}$) is given in bins of $p_T$ ($p$) and $R$ is a response matrix reflecting the relation between $p$ and $p_T$ bins. This averaging introduces some smoothing of the fractions as neighboring $p_T$ fractions have contributions from the same $p$ fractions, but the analysis is done in narrow $|\eta|$ intervals so only a few momentum bins contribute and the fractions depend only weakly on $p$; therefore, we consider the systematic effect of this procedure negligible. The fractions $f_{\text{id}}$ are shown in the bottom panel of Fig. 9. The transformation has little effect for $|\eta| < 0.2$, as expected, but we now observe that for $0.6 \leq |\eta| < 0.8$ the results are consistent.

FIG. 9. Uncorrected particle fractions as a function of momentum (top) and as a function of $p_T$ (bottom) for $|\eta| < 0.2$ (solid markers) and $0.6 \leq |\eta| < 0.8$ (open markers). Charged pions, kaons, and (anti)protons are plotted with circles, squares, and triangles, respectively. The error bars indicate the statistical uncertainty. Results for six centrality classes are presented.
TABLE II. Summary of the systematic uncertainties for the charged pion, kaon, and (anti)proton spectra and for the particle ratios. The different contributions are (a) event and track selection, (b) feed-down correction, (c) correction for muons, (d) parametrization of Bethe-Bloch and resolution curves, and (e) efficiency correction (same for all systems). Note that $K/\pi = (K^+ + K^-)/(\pi^+ + \pi^-)$ and $p/\pi = (p + \bar{p})/(\pi^+ + \pi^-)$. All values in percents.

with particle ratios being constant at midrapidity. We find that all four pseudorapidity intervals are consistent and the final fractions used to obtain the spectra in the next section are computed as the weighted average of the four pseudorapidity intervals.

8. Spectra

The invariant yields are obtained from the particle fractions using the relation

$$\frac{d^2N_{id}}{dp_Tdy} = J_{id}^{\epsilon_{ch}} f_{id} \times \frac{d^2N_{ch}}{dp_Td\eta}. \tag{5}$$
The first expression on the right-hand side is the input from the PID analysis, where \( \varepsilon_{\text{ch}} \) is the efficiency for (inclusive) identified charged particles and \( J_{id} \) is the Jacobian correction (from pseudorapidity \( \eta \) to rapidity \( y \)) and \( f_{id} \) is the fractional yield. The second expression is the fully corrected transverse momentum spectrum of inclusive charged particles that has already been published by ALICE [16]. The relative efficiency correction, \( \varepsilon_{\text{ch}}/\varepsilon_{id} \), was found to be consistent within \( \pm 3\% \) for all centrality classes and \( pp \) collisions, and for event generators: PYTHIA [52], PHOJET [53], and HIJING [54]. Thus, an average correction was used and a systematic uncertainty of 3\% was assigned. At high \( p_T \) the correction is nearly constant and on the order of 0.95. It is below 1 because the inclusive charged-particle spectra contain weakly decaying baryons such as \( \Sigma^+ \) that are not reconstructed with the charged-particle selection for primary particles. The proton and pion spectra have been corrected for feed-down from weak decays using MC simulations for the relative fraction of secondaries scaled to those extracted from distance-of-closest-approach MC template fits to data [44]. For \( p_T \approx 2 \) \( (3) \) GeV/c, the correction is approximately 0.3\% (4\%) for the pion (proton) yield and decreasing with increasing \( p_T \). Scaling between data and MC has a limited precision and could be different at higher \( p_T \). To be conservative, half of the correction is therefore assigned as a systematic uncertainty. This contribution to the systematic uncertainty is still small, as shown in Table II.

The efficiency and feed-down corrections are plotted in Fig. 10 as a function of \( p_T \) for central and peripheral Pb-Pb collisions. The Jacobian correction from \( \eta \) to \( y \), which has to be included for the lower \( p_T \) bins, is also shown and the largest effect is observed for protons, as expected. At \( p_T \approx 3 \) GeV/c, the correction is \( \approx 5\% \), \( \approx 1\% \), and \( \ll 1\% \) for protons, kaons, and pions, respectively.

### 9. Systematic uncertainties

The systematic uncertainty on the invariant yields has three main components: event and track selection, efficiency correction of the fractions, and the fraction extraction. Contributions from the event and track selection are taken directly from the inclusive charged particle result [16]. The systematic uncertainties for the corrections have been covered in the previous sections and are summarized in Table II. The systematic uncertainty on the fractions is mainly attributable to the uncertainties in the parametrization of the Bethe-Bloch and resolution curves used to constrain the fits. This systematic uncertainty can be attributable to calibration effects such that, for example, the \( \langle dE/dx \rangle \) does not depend on \( \beta \gamma \) alone; it can be related to the parametrizations not being able to describe the data properly, or it can be attributable to the statistical precision of the external PID data sets. To evaluate the uncertainty owing to these effects, the deviation of the fitted curves from the actual measured means and widths of
the $dE/dx$ spectra obtained from the analysis of the external pion, proton, and electron samples are used. Figure 11 shows the relative variations; all the available data were used for constructing the distributions; i.e., each of the six centrality classes and $pp$ collisions have four subsamples of tracks at different $|\eta|$. It was found that the precision of all these data sets is similar, so the final variation in systematic uncertainties for the same observable for different centrality classes and $set$ is similar, so the final variation in systematic uncertainties for the same observable for different centrality classes and $set$ is similar, so the final variation in systematic uncertainties for the same observable for different centrality classes and $set$ is similar, so the final variation in systematic uncertainties for the same observable for different centrality classes and $set$ is similar, so the final variation in systematic uncertainties for the same observable for differen
at the same $p_T$, there is a strong centrality dependence because the fractional yields also are lower for more central collisions. For the lower multiplicity intervals ($pp$ and 60%–80% centrality) this trend is broken because of the significant statistical uncertainty in the parametrized curves.

At high $p_T$ ($\approx 10$ GeV/$c$) the PID systematic uncertainty for kaons stays between 7% and 8% for Pb-Pb collisions and is around 5% for $pp$ collisions. For protons, the contribution is 16%–20% (except for 60%–80% Pb-Pb collisions, where it is 29% owing to a much larger statistical uncertainty in the fits to the external PID data).

**B. HMPID analysis of Pb-Pb data**

The HMPID is used to constrain the uncertainty of the charged pion, kaon, and (anti)proton measurements in the transition region between the TOF and TPC relativistic rise methods (in the region around $p_T = 3$ GeV/$c$). Thus, it both improves the precision of the measurement and validates the other methods in the region where they have the worst PID separation.

The HMPID [55] detector consists of seven identical proximity-focusing RICH (ring-imaging Cherenkov) counters. Photon and charged-particle detection is provided by a multiwire proportional chamber (MWPC) coupled to a CsI photocathode segmented into pads of size $0.8 \times 0.84$ cm$^2$ (the probability to obtain an amplified signals for an incident photon, the quantum efficiency, is $\approx 25\%$ for $\lambda_{ph} = 175$ nm). The amplification gas is CH$_4$ at atmospheric pressure with an anode-cathode gap of 2 mm; the operational voltage is 2050 V, corresponding to a gain of $\approx 4 \times 10^4$. It is located at about 5 m from the beam axis, covering a limited acceptance of $|\eta| < 0.5$ and $1.2^\circ < \varphi < 58.5^\circ$.

The HMPID analysis uses the 2011 Pb-Pb data with around $7.8 \times 10^6$ central triggered events (0%–10% centrality) and $5 \times 10^6$ semicentral triggered events (10%–50% centrality$^4$). The event and track selection is similar to the one described in Sec. II A 1, but in addition it is required that the tracks are propagated and matched to a primary ionization cluster in the MWPC gap of the HMPID detector (denoted matched cluster in the following). The matching efficiency, including spurious matches, is $\approx 95\%$ (see $\epsilon_{\text{match}}$ below). The matching criteria are tightened to reject the fake cluster-track matches, which account for $\approx 30\%$–40% (see $C_{\text{distance}}$ later), so that only tracks matched with their corresponding primary ionization cluster are identified. The PID in the HMPID is done by measuring the Cherenkov angle, $\theta_{\text{Ch}}$ [55], given by

$$\cos \theta_{\text{Ch}} = \frac{1}{n\beta} \Rightarrow \theta_{\text{Ch}} = \arccos \left( \frac{\sqrt{p^2 + m^2}}{np} \right),$$

where $n$ is the refractive index of the radiator used (liquid C$_6$F$_{14}$ with $n = 1.29$ at temperature $T = 20^\circ$C for photons $^4$To match centrality classes with the high-$p_T$ analysis, only spectra for 0%–40% are shown in this paper. Results for 20%–30%, 30%–40%, and 40%–50% are available on HepData.
with energy 6.68 eV). Figure 13 shows the Cherenkov angle as a function of the momentum for central Pb-Pb collisions.

The measurement of the single photon θCh angle in the HMPID requires knowledge of the track impact position and angle. These are estimated from the track extrapolation from the central tracking devices up to the radiator volume, where the Cherenkov photons are emitted. Only one matched cluster is associated with each extrapolated track, selected as the closest cluster to the extrapolated track point on the cathode plane, with a charge above ≈ 120σnoise. The cut on the charge excludes clusters from electronic noise and photons. The matching efficiency is defined for tracks extrapolated to the HMPID acceptance as

$$\varepsilon_{\text{match}} = \frac{N(\text{extrapolated with matched cluster})}{N(\text{extrapolated})}. \quad (7)$$

This efficiency is ≈95% and independent of momentum, particle species, and event multiplicity.

In Fig. 14, the residuals distribution between the track extrapolation and the matched cluster position in local chamber coordinates, X and Y, for tracks with $p_T > 1.5 \text{ GeV}/c$ is shown. The distributions have a resolution of $\sigma_{\text{res}} \approx 2$ cm. To reject fake cluster-match associations in the detector, mainly the situation when there is no correct signal to match, for example the particle, was absorbed or deflected in the material between the TPC and the HMPID detector, a selection on the distance, $\sqrt{X^2 + Y^2}$, computed on the cathode plane between the track extrapolation and the matched cluster is applied. This distance has to be less than 5 cm. This represents the best compromise between the loss of statistics and the probability of an incorrect association, where the latter becomes negligible (<0.1%) even in the most central collisions, as estimated from MC simulations. The distance cut leads to a correction factor

$$C_{\text{distance}} = \frac{N(\text{extrapolated with matched cluster distance} < 5 \text{ cm})}{N(\text{extrapolated with matched cluster})}, \quad (8)$$

for each momentum bin and does not depend on event multiplicity. Figure 15 shows this correction factor as a function of $p_T$ for positive and negative tracks integrated over the centrality classes (0%–50%).

Starting from the photon cluster coordinates on the photocathode, a backtracking algorithm calculates the corresponding emission angle. The Cherenkov photons are selected by the Hough transform method (HTM) [56], which for each track transforms the coordinates of photon hits into emission angles. The angle interval with the most hit candidates is selected and

FIG. 13. Cherenkov angle measured in the HMPID as a function of the momentum $p$ in 0%–10% central Pb-Pb collisions. The solid lines represent the theoretical curves for each particle species. The z axis indicated by the color scale is logarithmic.

FIG. 14. Distribution of the X (left) and Y (right) residuals between the matched cluster position and the closest extrapolated track point at the HMPID chamber plane (HMPID module 2), for positive and negative tracks with $p_T > 1.5 \text{ GeV}/c$ in Pb-Pb collisions (0%–50% centrality). The histograms have been scaled to have a similar maximum value. The small shift between positive and negative tracks in the Y residuals is attributable to a radial residual misalignment and an imperfect estimate of the energy loss in the material traversed by the track and is not corrected for in the calculation of the residual distance.

FIG. 15. The distance cut correction, $C_{\text{distance}}$, as a function of $p_T$ for positive (red) and negative (blue) tracks, respectively, in Pb-Pb collisions (0%–50% centrality).
\[\theta_{\text{Ch}}\] is computed as the weighted mean of the single photon angles. In central Pb-Pb collisions, where the total number of signals in the HMPID chambers is large, it is possible that the angle is constructed based on hits not corresponding to the Cherenkov photons associated with the track. This results in a significant reduction of the PID efficiency in the most central collisions. Figure 16 gives an example of the same effect in MC simulations. The response function consists of a Gaussian distribution for correctly assigned rings (signal) plus a distribution strongly increasing with the Cherenkov angle for incorrectly assigned rings (background). The signals from other tracks and photons in the same event are uniformly distributed on the chamber plane, and so the background rises with \[\theta_{\text{Ch}}\] because the probability of finding background clusters increases. The background contribution decreases with increasing track momentum because higher-momentum tracks give rise to a larger number of Cherenkov photons and have a smaller inclination angle, producing rings that are more likely to be fully contained inside the acceptance. As a result of this, the probability of incorrectly associating an angle computed from background clusters to the track decreases. The shoulder in the distribution starting at 0.7 rad is a boundary effect owing to the finite geometrical acceptance of the chamber.

Figure 17 gives examples of the reconstructed Cherenkov angle distributions in two narrow \(p_T\) intervals for different centrality classes; the reconstructed angle distribution is fitted with a sum of three Gaussian distributions, corresponding to the signals from pions, kaons, and protons, plus a distribution associated with the misidentified tracks that is modeled with a sixth-degree polynomial function that minimizes the reduced \(\chi^2\) of the fit.

The fitting is performed in two steps. In the first step, the initial parameters are based on the expected values. For the signal, the means \((\langle \theta_{\text{Ch}} \rangle_i)\) are obtained from Eq. (6), tuning the refractive index to match the observed Cherenkov angles, and the \(\sigma\) values \(\sigma_i\) are taken from the MC distribution in the given transverse momentum bin. The initial shape of the sixth-degree polynomial background is taken from MC simulations. Furthermore, the signal parameters are constrained to the ranges \([\langle \theta_{\text{Ch}} \rangle_i - \sigma_i, \langle \theta_{\text{Ch}} \rangle_i + \sigma_i]\) for the means and \([\sigma_i - 0.1\sigma_i, \sigma_i + 0.1\sigma_i]\) for the widths. After this first step, the \(p_T\) dependence of each parameter is fitted with a continuous function. In the second step, the fitting is repeated with only the yields as free parameters and constraining the mean and \(\sigma\) values to the continuous functions. The means and widths constrained in this way are all found to be independent of centrality, as shown in Fig. 18 for 0%–5% and 40%–50%
FIG. 17. Distributions of the Cherenkov angle measured in the HMPID for positive tracks having $p_T$ in the range 2.6–2.7 GeV/c (top) and in the range 3.8–4.0 GeV/c (bottom), for six different centrality classes: 0%–5%, 5%–10%, 10%–20%, 20%–30%, 30%–40%, and 40%–50%. The histograms have been scaled to have a similar maximum value. The shoulder in the distributions starting at 0.7 rad is a boundary effect owing to the finite chamber geometrical acceptance.

centrality classes. In Fig. 19, a comparison is shown between the mean values of the Cherenkov angle obtained from the fitting procedure with those obtained using a clean sample of protons and pions identified from $\Lambda$ and $K^0_S$ decays.

To correct for the incorrectly assigned Cherenkov rings, a PID efficiency is used. This efficiency has to be derived from a data set containing identified particles of a single species, so one can use MC or $V^0$ daughters. For such a clean set of particles that passes the distance cut, e.g., MC pions as in Fig. 16, the PID efficiency is

$$\varepsilon_{\text{PID}} = \frac{N(\text{signal})}{N(\text{signal and background})},$$

where the signal is the integral of the Gaussian fit function. The PID efficiency has been evaluated from MC simulations that reproduce the background observed in the data well. A data-driven cross-check of the efficiency has been performed using a clean sample of $V^0$ daughter tracks. The comparison between data and MC is shown in Fig. 20 for 0%–5% and 40%–50% centrality classes and shows good agreement. We also observe that, as expected, the efficiency decreases for more central collisions owing to the occupancy effects mentioned above. The maximum value of the PID efficiency is $\approx 80\%$ at $p_T \sim 6$ GeV/c in the 40%–50% centrality class. As an additional check of the PID efficiency, the ratio between the raw yields extracted from the fit (signal) corrected by the PID efficiency and the total entries in the original histogram (signal and background) has been evaluated for each $p_T$ bin for all centralities. The ratio is consistent with unity when the systematic uncertainties listed in Table III are taken into account.

The systematic uncertainty for the HMPID analysis has contributions from tracking and PID. These uncertainties have been estimated by individually changing the track selection cuts and the parameters of the fit function used to extract the raw yields. The means of the Gaussian functions have been changed by $\pm \sigma$. Similarly, the widths of the Gaussian
functions have been varied by ±10%, accounting for the maximum expected variation of the resolution as a result of the different running conditions of the detector during data acquisition that can have an impact on the performance. When the means are changed, the widths are fixed to the default value, and vice versa. The parameter variation is performed for all three particles species. In addition, the uncertainty on the association of the track to the matched cluster is obtained by varying the value of the distance cut required for the match by ±1 cm. These contributions do not vary with the collision centrality.

To estimate the uncertainty owing to the incomplete knowledge of the shape of the background distribution, an effective PID efficiency for pions (top) and protons (bottom) selected exploiting $V_0$ decay properties, compared with the MC results for primary tracks for 0%–5% and 40%–50% centrality classes.

alternative background function, depending on $\tan(\theta)$ and derived from geometrical considerations in case of orthogonal tracks [55], has been used,

$$f(\theta) = a + b \times \tan \theta + c \times [\tan \theta(1 + \tan^2 \theta)]^d,$$

(10)

where $a$, $b$, $c$, and $d$ are free parameters. The corresponding systematic uncertainty reaches a maximum value at low momenta for the most central collisions ($\approx$15% for pions and $\approx$8% for kaons and protons). The systematic uncertainty decreases with $p_T$ because, as previously explained, the background contribution decreases with increasing track momentum. A summary of the different contributions to the systematic uncertainty for the HMPID Pb-Pb analysis is given in Table III.

III. RESULTS AND DISCUSSION

The measurement of charged pion, kaon, and (anti)proton transverse momentum spectra has been performed via several independent analyses, each one focusing on a subrange of the total $p_T$ distribution, using individual detectors and specific techniques to optimize the signal extraction (see Table IV). The results were combined in the overlapping ranges using a weighted average with the independent systematic uncertainties as weights (a 3% common systematic uncertainty owing to the TPC tracking is added directly to the combined spectrum). The statistical uncertainties are much smaller and therefore neglected in the combination weights. For $p_T > 4$ GeV/$c$ only the TPC $dE/dx$ relativistic rise analysis is used for all species. Figure 21 shows the ratio of individual spectra to the combined spectrum for the 0%–5%, 20%–40%, and 60%–80% central Pb-Pb data, illustrating the compatibility between the different analyses. In the centrality intervals where the HMPID measurements are available, they improve the systematic uncertainty of the kaon and proton yields by approximately a factor of two in the $p_T$ region where it is later observed that the peaks of the kaon-to-pion and the proton-to-pion ratios are located (see Figs. 25 and 26). We note that the final charged-pion spectra are consistent with the neutral-pion spectra scaled by a factor of two within statistical and systematic uncertainties [57].

FIG. 21. The ratio of individual spectra to the combined spectrum as a function of $p_T$ for pions (top row), kaons (middle row), and protons (bottom row). From left to right the columns show 0%–5%, 20%–40%, and 60%–80% (where there are no HMPID results). Only the $p_T$ range where the analyses overlap is shown. For $p_T > 4$ GeV/$c$, no combination is done and the TPC $dE/dx$ relativistic rise results are used directly, which gives rise to a small discontinuity for protons at this $p_T$. The ITS + TPC + TOF spectra are the results published in Ref. [44]. The statistical and independent systematic uncertainties are shown as vertical error bars and as a band, respectively, and only include those on the individual spectra.
FIG. 22. Transverse momentum spectra of charged pions (left), kaons (middle), and (anti)protons (right) measured in Pb-Pb and pp collisions at √sNN = 2.76 TeV. The systematic and statistical error are plotted as color boxes and vertical error bars (hard to see), respectively. The spectra have been scaled by the factors listed in the legend for clarity.

The final combined transverse momentum distributions for the three particle species are shown in Fig. 22. For p_T < 3 GeV/c, a hardening of the spectra is observed going from peripheral to central events. This effect is mass dependent and is characteristic of hydrodynamic flow, as discussed in Ref. [44]. For high p_T (>10 GeV/c) the spectra follow a power-law shape, as expected from perturbative QCD (pQCD) calculations. In the following, the high-p_T results are first discussed before going on to the intermediate p_T region.

A. The high-p_T results

To study jet quenching at high p_T, the nuclear modification factor, R_AA, is constructed. The R_AA is

\[ R_{AA} = \frac{d^2N_{id}^{AA}/dyd\pT}{\langle T_{AA}\rangle d^2\sigma_{pp}^{\text{id}}/dyd\pT}, \]

where \( N_{id}^{AA} \) and \( \sigma_{pp}^{\text{id}} \) are the charged-particle yield in nucleus-nucleus (A-A) collisions and the cross section in pp collisions,
FIG. 24. The nuclear modification factor $R_{AA}$ as a function of $p_T$ for charged pions, compared with PHENIX results for neutral pions [65]. Results for different collision centralities are shown. Statistical and PID systematic uncertainties are plotted as vertical error bars and boxes around the points, respectively.

respectively, and $\langle T_{AA} \rangle$ is the nuclear overlap function. The latter is obtained from a Glauber model [58] and is related to the average number of binary nucleon-nucleon collisions ($N_{\text{coll}}$) and the inelastic nucleon-nucleon cross section as $
abla N_{\text{col}}/\nabla N_{\text{inel}}$.

Figure 23 shows the $R_{AA}$ for all centrality classes. The results show that for all centrality classes any particle species dependence of the nuclear modification for $p_T > 10$ GeV/c is small, compared with the large suppression ($R_{AA} \ll 1$). This suggests that jet quenching does not produce signatures that affect the particle species composition for the leading particles. The results presented in this paper are all done at the particle level, while for some models that motivated these studies the predictions are done for jets, e.g., the Sapeta-Wiedemann model [22]. It is not obvious how to compare the results presented here with such calculations. In the following we therefore discuss how inclusive $p_T$ spectra compare with inclusive jet $p_T$ spectra. In particular, it is examined if the results are likely to be affected by a quenched jet fragmentation bias (if quenched jets emit less high-$p_T$ particles than unquenched ones) or a surface bias (if unquenched jets from the surface dominate).

At the LHC, by studying dijets in Pb-Pb collisions and selecting on the dijet asymmetry, one can study samples with large asymmetries where one knows, based on comparisons with $pp$ results, that at least the subleading jet has suffered a large energy loss [8,9]. The study of the fragmentation functions (FFs) for these quenched jets has shown that for charged tracks with $p_T > 4$ GeV/c they are similar to those observed in $pp$ collisions for subleading jets with $p_{T,jet} > 50$ GeV/c [59], in agreement with what one also finds for inclusive jets [60]. This rules out a large fragmentation bias (for lower jet $p_T$ see below) and suggests that any surface bias is the same as for inclusive jets. To understand the jet $p_T$ covered by the results presented here, one can now, thanks to the similarity of the FFs in $pp$ and Pb-Pb collisions, rely on NLO pQCD calculations for $pp$ collisions. The FFs found to best describe the inclusive charged particle spectra [61] are the Kretzer distributions [62]. NLO pQCD calculations using the Kretzer FFs suggest that more than half of the particles with $p_T$ between 10 and 20 GeV/c are from gluon jets and that the typical jet $p_T$ is roughly a factor of 2–3 larger than the hadron $p_T$ ($\langle z \rangle = p_T/\langle p_T \rangle$) [61]. The conclusions for jets with $p_{T,jet} > 50$ GeV/c are therefore expected to be directly applicable also for the highest-$p_T$ particles studied here. ALICE has studied charged jets in Pb-Pb collisions where it was found that requiring a minimum one track with $p_T > 10$ GeV/c in a jet gives the same fragmentation bias of the jet reconstruction efficiency in Pb-Pb collisions as in PYTHIA for $20 < p_T < 110$ GeV/c [63], so there is no evidence even for lower $p_T$ jets that there is a different fragmentation bias in Pb-Pb collisions than in $pp$ collisions. The results in Fig. 23 therefore indicate that for jets with final $p_T$ of order 25 to 50 GeV/c, jet quenching does not produce large particle-species-dependent effects in the hard core of the jet where leading particle production mainly occurs.

To be able to set stronger constraints, one needs theoretical modeling. As the $R_{AA}$ for charged pions, kaons, and protons reported here for $p_T > 10$ GeV/c are all compatible to the $R_{AA}$ for inclusive charged particles [16] and neutral pions [57],

---

5 The publication contains only calculations for $\sqrt{s} = 900$ GeV and $\sqrt{s} = 7$ TeV that have been averaged as an approximate estimate for the energy of $\sqrt{s} = 2.76$ TeV shown here because the energy dependence is not that strong.
we refer to these papers for comparisons with models without large particle-species-dependent effects. When compared with models which include large particle-species-dependent effects, the results indicate that the jet-quenching mechanism does not involve direct exchange of quantum numbers with the medium, and there are also no indications of a modified color structure of the fragmentation [22] or that the probe is excited to other color states [23]. Models in which the hadronization of jet fragments occurs in the medium also appear to be ruled out [24]. It seems that the medium quenches the jet as a whole rather than directly interacting with its fragments. Such a picture has recently been proposed [64], arguing that the medium typically cannot resolve the structure inside the hard core of the jet such that all fragments lose energy coherently.

In Fig. 24, the $R_{AA}$ for charged pions, the most precise measurement in this work and the one least sensitive to radial flow, is compared with the $R_{AA}$ for neutral pions measured by PHENIX [65] at the RHIC. The ALICE results are systematically below the PHENIX values for $p_T < 10 \text{ GeV}/c$.

$^6$ The results have been obtained from the tables at the PHENIX web site and the 5%–10% data set has been constructed from the 0%–5% and 0%–10% data sets.
FIG. 26. (Anti)proton to charged pion ratio as a function of transverse momentum (solid markers). The top panels show the full pp with the pp results (open markers) overlaid in the most central and the most peripheral centrality class. In the bottom panels the Pb-Pb results for \(p_T < 8 \text{ GeV/c}\) are compared with EPOS model 2.17-3 (line). The systematic and statistical error are plotted as color boxes and vertical error bars, respectively.

but consistent within systematic uncertainties for larger \(p_T\). We note that the relative centrality evolution is similar at the two center-of-mass energies. In Ref. [66], a simple study of the \(R_{AA}\) at \(p_T = 10 \text{ GeV/c}\) found that the energy loss is \(\approx 40\%\) larger at the LHC than at the RHIC in all centrality classes (it scales as \(\sqrt{dN/d\eta}\) for a fixed initial geometry).

The proton-to-pion and the kaon-to-pion ratios as a function of \(p_T\) are shown in Figs. 25 and 26. The similarity at high \(p_T\) for the \(R_{AA}\) implies that the particle ratios there are also the same in \(pp\) and Pb-Pb collisions. Because the particle ratios are independent of \(p_T\) in this region, we use the integrated particle ratios for \(p_T > 10 \text{ GeV/c}\) to elucidate the precision with which the suppression of pions, kaons, and protons is similar; see Fig. 27. The advantage of using particle ratios is that the results for heavy-ion collisions can be shown separately from the \(pp\) results. Furthermore, in the ratios the systematic uncertainty associated with the inclusive charged-particle \(p_T\) spectra normalization cancels. All the steps in the high-\(p_T\) \(dE/dx\) analysis discussed in Sec. II A are done independently for each centrality class (using disjunct data sets) so one does not expect any direct correlations of the results. We conclude that all kaon-to-pion (proton-to-pion) ratios as a function
FIG. 27. The integrated particle ratios for $p_T > 10\text{ GeV/c}$ in $pp$ and $\text{Pb-Pb}$ collisions as a function of the number of participants. (Left) The kaon-to-pion ratio. (Right) The proton-to-pion ratio scaled by a factor of 3 for clarity. Statistical and PID systematic uncertainties are plotted as vertical error bars and boxes around the points, respectively. Note that this kaon-to-pion (proton-to-pion) “high-$p_T$” ratio is $\approx 10$ ($\approx 2$) times larger than the bulk ratio [44].

of $N_{\text{part}}$ are consistent within the systematic uncertainty of $\approx 10\%$ ($\approx 20\%$). Measurements with improved precision using Run 2 and Run 3 LHC data could reveal possible subtle particle-species differences.

B. The intermediate $p_T$ results

In the following, the intermediate $p_T$ regions in Figs. 25 and 26, where the proton-to-pion and the kaon-to-pion ratios are enhanced, are discussed.

The observation of the large proton-to-pion ratio at intermediate $p_T$ at the RHIC generated numerous speculations that the degrees of freedom in the medium are constituent quarklike and that they recombine when hadronizing to give rise to distinct meson and baryon properties. As the $\phi$ meson has a mass similar to that of a proton, it is crucial in testing these ideas and results at the RHIC indeed seemed to confirm this picture [67], while at LHC the picture appears to be more complicated [68,69]. Some of the models developed to describe results at the RHIC have been extended to the LHC energies. One can, in general, separate recombination models into two classes. In soft models, recombination only occurs for soft thermal radially flowing partons. In Ref. [68] ALICE showed calculations for such a model [31] and the prediction is that at the LHC energies the particle ratios in central collisions are similar to those measured at the highest RHIC energy. In hard recombination models, jet fragments can recombine with both partons from the medium and other jets. At LHC energies, the minijet activity is much larger than at RHIC energies, which motivated predictions for central collisions of particle ratios an order of magnitude larger ($p/\pi \sim 10-20$) than the peak values reported here and persisting out to much higher $p_T$ [34]. The failure of hard recombination is in qualitative agreement with the picture where the jet interacts with the medium as a whole so that the hard fragments of the jet cannot recombine with partons in the medium or in another jet.

EPOS [70] is a full MC generator which contains both soft and hard physics. It incorporates a hydrodynamical phase and additional hadronization processes at intermediate $p_T$ where the interaction between bulk matter and quenched jets is considered [71]. This interaction introduces a baryon-meson effect, where fully quenched jets are allowed to hadronize with flowing medium quarks. When we study the full set of ratios at all centralities (Figs. 25 and 26) EPOS generally reproduces the centrality dependence well, even for very peripheral events, where it is known that pure hydrodynamical calculations fail to describe the data [44]. However, EPOS overpredicts the magnitude of both the proton-to-pion and the kaon-to-pion peak; it is therefore critical to understand how important the additional hadronization processes are, relative to the hydrodynamic flow, when all parameters have been tuned.

Figure 28 shows a comparison of particle ratios with results from STAR [25] and PHENIX [27] at the RHIC measured in Au-Au collision at $\sqrt{s_{NN}} = 200\text{ GeV}$. In both cases, the results have been averaged for both charge signs for pions and protons. We use the STAR feed-down-corrected data for this comparison. The proton-to-pion peak at the LHC is approximately $20\%$ larger than at the RHIC, which is consistent with an increased average radial flow velocity. At high $p_T$, the systematic uncertainties of the STAR data are very large and it was noted in a later publication that they might even be underestimated [26]. Interestingly, there is no evidence for a peak in the kaon-to-pion ratio measured by PHENIX, which is similar to the ALICE data points for $p_T \leq 3\text{ GeV/c}$, but continues to rise in the few data points above this $p_T$.

Careful modeling of $p_T$ spectra and azimuthal flow is needed to answer the question of whether there are additional hadronization processes such as soft recombination at the LHC. Because the multiplicity evolution of particle ratios in $p$-Pb collisions is similar to what is observed for Pb-Pb collisions [37], it would be interesting to include those results in the modeling, in particular, because there is no indication of jet quenching [73], which conceptually simplifies the problem.

\footnote{Values taken from https://drupal.star.bnl.gov/STAR/files/ starrpublications/65/data.html for protons and a similar feed-down correction has been assumed for antiprotons.}

\footnote{We note that in a recent preprint it is shown that soft recombination together with pQCD + quenching can give a good description of pion, kaon, and (anti)proton spectra in central heavy-ion collisions at both the RHIC and the LHC for $1.5 < p_T < 10\text{ GeV/c}$ [72].}
IV. CONCLUSION

We have reported the centrality-dependent measurement of charged pions, kaons, and (anti)protons at large transverse momenta in Pb-Pb collisions at the LHC. When combined with previously published data at lower \( p_T \), the new results provide a comprehensive data set of pion, kaon, and (anti)proton \( p_T \) spectra with unprecedented systematic precision and \( p_T \) reach. The spectra are sensitive to physics mechanisms that differentiate between baryons and mesons, strange and nonstrange, or heavy and light hadrons.

At high \( p_T \) (\( p_T > 10 \text{ GeV}/c \)), particle ratios and nuclear modification factors allow the study of effects related to jet quenching. The measurements in this \( p_T \) range do not show any difference in the nuclear modification factor for pions, kaons, and protons. A comparison of the present results with jet measurements and theoretical calculations establishes that jet quenching does not introduce large species-dependent modifications for leading particles. Instead, at high \( p_T \), for all six centrality classes and the \( pp \) data analyzed here, the same kaon-to-pion and proton-to-pion ratios are obtained within a systematic precision of \( \approx 10\%-20\% \).

At intermediate \( p_T \), calculations are needed to determine whether models containing only hydrodynamics and jet quenching can provide a good description across many observables of the available experimental results or if additional processes such as recombination are needed. Because the initial geometry of the collision directly affects both the flow and the energy loss, the centrality dependence presented in this paper is important for constraining both the low-\( p_T \) hydrodynamics and the high-\( p_T \) jet quenching in the calculations.

The results in this paper, taken together with the wealth of other high \( p_T \) and jet results from the LHC, point toward a need for further development of a microscopic QCD-based picture that explains in detail the relation between the jet, the medium, and the energy loss.

ACKNOWLEDGMENTS

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration. 96 Pusan National University, Pusan, South Korea
97 Research Division and ExtreMe Matter Institute EMMI, GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt, Germany
98 Radjer Bošković Institute, Zagreb, Croatia
99 Russian Federal Nuclear Center (VNIIEF), Sarov, Russia
100 Russian Research Centre Kurchatov Institute, Moscow, Russia
101 Saha Institute of Nuclear Physics, Kolkata, India
102 School of Physics and Astronomy, University of Birmingham, Birmingham, United Kingdom
103 Sección Física, Departamento de Ciencias, Pontificia Universidad Católica del Perú, Lima, Peru
104 Sezione INFN, Bari, Italy
105 Sezione INFN, Bologna, Italy
106 Sezione INFN, Cagliari, Italy
107 Sezione INFN, Catania, Italy
108 Sezione INFN, Padova, Italy
109 Sezione INFN, Rome, Italy
Sezione INFN, Trieste, Italy
Sezione INFN, Turin, Italy
112 SSC INRHEP of NRC Kurchatov institute, Protvino, Russia
113 SUBATECH, Ecole des Mines de Nantes, Université de Nantes, CNRS-IN2P3, Nantes, France
114 Suranaree University of Technology, Nakhon Ratchasima, Thailand
115 Technical University of Košice, Košice, Slovakia
116 Technical University of Split FESB, Split, Croatia
117 The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Cracow, Poland
118 The University of Texas at Austin, Physics Department, Austin, Texas, USA
119 Universidad Autónoma de Sinaloa, Culiacán, Mexico
120 Universidade de São Paulo (USP), São Paulo, Brazil
121 Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil
122 University of Houston, Houston, Texas, USA
123 University of Jyväskylä, Jyväskylä, Finland
124 University of Liverpool, Liverpool, United Kingdom
125 University of Tennessee, Knoxville, Tennessee, USA
126 University of the Witwatersrand, Johannesburg, South Africa
127 University of Tokyo, Tokyo, Japan
128 University of Tsukuba, Tsukuba, Japan
129 University of Zagreb, Zagreb, Croatia
130 Université de Lyon, Université Lyon 1, CNRS/IN2P3, IPN-Lyon, Villeurbanne, France
131 V. Fock Institute for Physics, St. Petersburg State University, St. Petersburg, Russia
132 Variable Energy Cyclotron Centre, Kolkata, India
133 Vinča Institute of Nuclear Sciences, Belgrade, Serbia
134 Warsaw University of Technology, Warsaw, Poland
135 Wayne State University, Detroit, Michigan, USA
136 Wigner Research Centre for Physics, Hungarian Academy of Sciences, Budapest, Hungary
137 Yale University, New Haven, Connecticut, USA
138 Yonsei University, Seoul, South Korea
139 Zentrum für Technologietransfer und Telekommunikation (ZTT), Fachhochschule Worms, Worms, Germany

*Deceased.
† Also at M.V. Lomonosov Moscow State University, D.V. Skobeltsyn Institute of Nuclear, Physics, Moscow, Russia.
‡ Also at University of Kansas, Lawrence, Kansas, USA.
