We re-analyse high redshift and high resolution Lyman-α forest spectra considered in [1], seeking to constrain the properties of warm dark matter particles. Compared to this previous work, we consider a wider range of thermal histories of the intergalactic medium. We find that both warm and cold dark matter models can explain the cut-off observed in the flux power spectra of high-resolution observations equally well. This implies, however, very different thermal histories and underlying reionization models. We discuss how to remove this degeneracy.

1. Introduction

Dark matter is a central ingredient of the current standard cosmological model. It drives the formation of structures, and explains the masses of galaxies and galaxy clusters. If dark matter is made of particles, these yet-unseen particles should have been created in the early Universe long before the recombination epoch. If such particles were relativistic at early times, they would stream out from overdense regions, smoothing out primordial density fluctuations. The signature of such warm dark matter (WDM) scenario would be the suppression of the matter power spectrum at scales below their free-streaming horizon. From cosmological data at large scales (CMB and galaxy surveys) we know that such a suppression should be sought at comoving scales well below a Mpc.

The Lyman-α forest has been used for measuring the matter power spectrum at such scales [2–4]. In previous works only upper bounds had been reported on the mass of the thermal relic [5–10]. However, while in the SDSS spectra there is no cut-off in the transmitted flux power spectrum, there is a cut-off in the high resolution spectra, for example [4,11,7]. Recently [1] has observed the cut-off of the flux power spectrum at scales k ∼ 0.03 s/km and redshifts z = 4.2–5.4.

However, the Lyman-α forest method measures not the distribution of dark matter itself, but only the neutral hydrogen density as a proxy for the overall matter density. The process of reionization heats the hydrogen and prevents it from clustering at small scales at the redshifts in question [12]. Therefore, the observed hydrogen distribution eventually stops to follow the DM distribution. Indeed, it was demonstrated in [1] that within ΛCDM cosmology there exists a suitable thermal history of intergalactic medium (IGM) that is consistent with the observed cutoff. This does not mean, however, that this scenario is realized in nature.

In this Letter we investigate this issue in depth. We ask whether the cutoff in the flux power spectrum can be attributed to the suppression of small scales with warm dark matter and what this means for the thermal history of IGM. To this end we reanalyze the data used in [1]. We use the same suite of hydrodynamical simulations of the IGM evolution with cold and warm dark matter models as in [1] and demonstrate that the data is described equally well by the model, where flux power spectrum suppression is mainly due to WDM.

2. Data and model

The data set is constituted by 25 high-resolution quasar spectra, in the redshift interval 4.48 ≤ zSO ≤ 6.42. The spectra were taken with the Keck High Resolution Echelle Spectrometer (HIRES) and the Magellan Inamory Kyocera Echelle (MIKE) spectrograph on the Magellan clay telescope. The QSO spectra are divided into four
redshift bins centered on: \(z = 4.2, 4.6, 5.0, 5.4\). The resulting range of wave-numbers probed by this dataset is \(k = 0.005–0.08\) \(\text{km/s/km}\).

At these redshifts, the IGM is thought to be in a highly ionized state, being photo-ionized and photo-heated by early sources. Both the WDM cosmology and the IGM temperature affect the amount of flux power spectrum at small scales through three distinct physical mechanisms: (1) a suppression in the initial matter power spectrum; (2) Jeans broadening; and (3) Doppler broadening of the absorption lines [12–17]. The first mechanism is cosmological, the latter two are astrophysical. The Doppler broadening is a one dimensional smoothing effect that originates from observing the hot IGM along a line of sight. The Maxwellian distribution of velocities in the gas then leads to the broadening effect. The Jeans broadening smooths the three-dimensional underlying gas distribution relative to the dark matter.

The level of ionization is captured by the effective optical depth, \(\tau_{\text{eff}}\), that is computed from the mean flux, \(\langle F \rangle\), through the relation \(\langle F(z) \rangle = \exp(-\tau_{\text{eff}}(z))\). Because the IGM spans a wide range of density, describing the IGM temperature may be complicated in principle. But, assuming that the IGM is heated by photo-heating, the temperature of the IGM follows a simple power-law temperature-density relation [18]:

\[
T(\delta) = T_0(z) \left(1 + \delta \right)^{\gamma(z)-1},
\]

where \(\delta = \delta_{\text{m}}/\bar{\rho}_{\text{m}}\) is the matter overdensity and \(T_0(z)\) and \(\gamma(z)\) are unknown functions of redshift. The results of Ref. [1] are based on single power-law parametrizations, \(T_0(z)\) and \(\gamma(z)\). In this letter we let the parameters of the IGM thermal state vary independently in each redshift bin, with a total of 8 parameters describing the IGM thermal state \(T_0(z_i)\) and \(\gamma(z_i)\) in 4 distinct redshift intervals.

We want to point out that \(T_0\) and \(\gamma\) are not varied in post-processing. The original work of [1] considered 9 simulation runs with distinct thermal histories for each cosmology considered. The different thermal histories are realized by changing the photo-heating function in the simulations. The resulting values of \(T_0\) and \(\gamma\) are approximately distributed on a regular grid. In [1] the effect of Jeans smoothing is accounted by considering two additional simulation runs, where the time at which the ultraviolet background is switched on, \(z_{\text{reion}}\), is varied. We caution the reader that the resulting constraints on \(z_{\text{reion}}\) must not be intended as a measurement of the time of reionization, because this depends on the details of the implementation of the ultraviolet background. Instead, varying \(z_{\text{reion}}\) must be considered as a way to account for the unknown level of Jeans smoothing. Finally, as in [1], we allow the effective optical depth vary independently in each redshift bin, \(\tau_{\text{eff}}(z_i)\).

It should be noted that this interpolation scheme between simulations with different temperatures may also vary the amount of Jeans broadening (also known as the “filtering scale”). While the degeneracy between the WDM cosmologies and the Doppler smoothing has been extensively considered in the literature, the degeneracy between Jeans smoothing and WDM cosmology has not been considered in depth so far. In particular this has not been done for the suite of simulations in the original work [1] on which we base our analysis. We leave the study of the degeneracy between the Jeans smoothing and WDM for future work.

The results also depend on the cosmological parameters \(n_s\), \(\Omega_M\), \(\sigma_8\), \(H_0\). However the small scale Lyman-\(\alpha\) data by itself does not sufficiently constrain the cosmological parameters. Therefore, in the final likelihood function for these parameters we used

\[1\] Ref. [1] also performed such a “binned analysis”, see the detailed comparison below.

**Fig. 1.** Measured flux power spectrum in dimensionless units, \(\Delta^2(k) = P_f(k) \times k^3/\pi\), compared with the theoretical model with the best-fitting values of the astrophysical and cosmological parameters for WDM and CDM cosmologies. The solid red line shows the best-fitting values for WDM cosmology. The dotted lines refer to the best-fitting case for CDM cosmology. These best-fitting models largely overlap, except at the highest redshift and on the smallest scales. The blue, gray and green points are SDSS-III/BOSS DR9 data for \(z = 4.0\), \(z = 4.2\) and \(z = 4.4\) from [20]. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

**3. Results**

In Table 1 we give the result of the parameter estimation. Fig. 1 shows the theoretical flux power spectrum for the mean values of the parameters, compared with the MIKE and HIRES data used in this analysis. In order to clarify the effect of different thermal histories on our constraints, we show the effect of changing the thermal parameters \(T_0\) and \(\gamma\) and ionization parameters \(\tau_{\text{eff}}\) and the mass of the thermal relic (1/\(m_{\text{wdm}}\)) in Fig. 2, analogous to Figs. 5 and 6 of [1].

In Fig. 3 we show the 2D confidence regions between \(m_{\text{wdm}}\), and \(T_0 = T(\delta = 0)\) (marginalizing over the other parameters). We see that at redshifts \(z = 4.2, 4.6\) there is no degeneracy and an IGM temperature \(T_0 \approx 10^4\) K is needed to explain the observed flux power spectrum independently of \(m_{\text{wdm}}\). If dark matter is “too warm” (\(m_{\text{wdm}} < 1.5\) keV) it produces too sharp of a cut-off in the power spectrum and is inconsistent with the data.

At the \(z = 5.0\) bin the situation is different. For the masses \(m_{\text{wdm}} \approx 2.2–3.3\) keV even very low temperatures \(T_0 \lesssim 2500\) K are consistent with the data. In this case the cutoff in the flux power spectrum is explained by WDM rather than by the temperature. The situation is analogous at \(z = 5.4\). Table 1 summarizes the parameter estimation.
Fig. 2. Effect of the IGM parameters and $m_{\text{wdm}}$ on the flux power spectrum in dimensionless units, $\Delta^2(k) = P_{\gamma}(k) \times k^2/\pi$. In the top-left (top-right, bottom-left, bottom-right) panel we show the effect of varying $T_0$ ($\gamma$, $T_{\text{eff}}$, $1/m_{\text{wdm}}$) by ±10% with respect to the best-fitting values for WDM cosmology. The solid line corresponds to the best-fitting case for WDM cosmology, the dashed (dotted) line corresponds to the relevant parameter increased (decreased) by 10%. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Fig. 3. Confidence regions between $m_{\text{wdm}}$, and $T_0$ and $\gamma$ at all redshift, and $z_{\text{reion}}$. We show $1/m_{\text{wdm}}$ instead of $m_{\text{wdm}}$ for visualization purposes. $m_{\text{wdm}}$ is degenerate with $z_{\text{reion}}$, that is the redshift at which the ultraviolet background has been switched on in the simulations, and $T_0$ at the redshift $z=5.0$. $m_{\text{wdm}}$ is not degenerate with the $T_0$ for the other redshift intervals. There is no obvious degeneracy with $\gamma$. Regarding $m_{\text{wdm}}$ and $T_0$, at the redshifts $z=4.2$, 4.6 there is no degeneracy and $T_0 \sim 10^4$ K is needed to explain the observed flux power spectrum, independently of $m_{\text{wdm}}$. At $z=5.0$ even very low temperatures $T_0 \lesssim 2500$ K are consistent with the data, and the cutoff in the flux power spectrum is explained by WDM rather than by the temperature. At $z=5.4$ the analysis prefers low values of $T_0 \sim 5 \times 10^3$ K, independently of $m_{\text{wdm}}$. 
Fig. 4. The evolution of the IGM mean temperature, T₀, in redshift. Black vertical bars are 1-σ confidence limits; red vertical bars are 2-σ confidence limits. Filled dots are the parameter mean; the arrows mark the upper limits. The horizontal bars span the redshift interval of Lyman α absorbers considered for each measurement of the flux power spectrum. The solid (dotted) lines refer to the constraints on temperature for WDM (CDM) cosmology (the constraints in CDM have been shifted by z = 0.05 for improving the readability of the figure). At z = 5.0 there is a 1-σ level detection and only an upper limit at 2-σ level in WDM cosmology, instead there are both 1 and 2-σ detections for CDM cosmology. At z = 5.4, there are only upper limits at 1 and 2-σ levels for WDM cosmology and 1-σ detection and 2-σ upper limit for CDM cosmology. Hence, the constraints on the temperature are substantially equivalent in the two cosmologies. The blue dashed line is the asymptotic IGM mean temperature in the case of early hydrogen and first helium reionization from a stellar ionizing spectrum with slope α = 2, being the ionizing spectrum f_{ν} ∝ ν^{-1.5}. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Another important property of Fig. 3 is that even assuming CDM cosmology, the temperature T₀ is a non-monotonic function of redshift and should be colder than ~ 8000 K at z = 5.0–5.4, see Fig. 4. The resulting χ² for the Bayesian analysis is ~ 25, for 30 degrees of freedom (49 data points - 19 free parameters). This is in agreement with the fact that the covariance matrix is uncertain and that has been multiplied by a factor that boosts the resulting error bars by 30%, with respect to the error bars computed by bootstrapping. This is done in the original analysis in order to account for presumed sample variance effect that affect other statistics like the transmitted flux PDF. The sample variance effect may affect the transmitted flux power spectrum, even if a detailed computation has not been performed.

For completeness we have also performed frequentist analysis for the same χ² considered in the Bayesian analysis. As shown in Fig. 5 the two analyses are in broad agreement with each other.

We would like to stress that our results depend crucially on allowing for a non-monotonic redshift dependence of T₀(z). In [1], it was shown that assuming a power-law (monotonic) redshift dependence for T₀(z) and y(z), one predicts higher temperatures of IGM for the same data. In this case the CDM cosmology is preferred over WDM, leading to the 2σ lower bound m_{WDM} ≥ 3.3 keV [1]. The “binned analysis” of [1] gave results similar to those, reported here. The authors of [1] however rejected these results, considering a temperature jump at z = 5–5.4 to be “unphysical” and arguing that the low χ² is a sign of overfitting.

In our opinion the present analysis implies that more data is needed to study such a scenario, as it currently does not allow to make any definitive conclusion and in particular does not allow to rule it out. Moreover, as mentioned above, the error bars in [1] were inflated by 30% and therefore we consider the reduced χ² = 25/30 ≈ 0.83 to be consistent with 1. We see that 2σ lower bound on the WDM mass relaxes down to m_{WDM} ≥ 2.1 keV (consistently with the results of binned analysis of [1]). Moreover, the non-monotonic thermal history makes the WDM with m_{WDM} = 2–3 keV an equally good fit as CDM. The best fit values of T₀ can be inaccurate as they lie below the lowest simulation point in T₀ grid. Therefore more simulations are needed to settle this question. This is currently work in progress. In the absence of such additional studies the proposed non-monotonic thermal history cannot be ruled out based on the existing Lyman-α data.

For the interpretation of these results it is crucial to overview what is known about the thermal state of the IGM both theoretically and observationally. We argue below that the measured thermal history is in agreement with current models of galaxy formation and reionization.

Fig. 5. The results of the frequentist analysis: the χ² − χ²_{min} versus the WDM mass, m_{WDM}. There are two minima of the χ² curve, CDM and m_{WDM} = 2.7 keV.

4. State of the IGM at z ∼ 5

The IGM temperature can be determined from the broadening of the Lyman-α absorption lines in QSO spectra [21–31.16]. Alternatively, it has been proposed to determine the IGM temperature by measuring the level of the transmitted flux [32–34,30], however there is no agreement between the two methods yet, see [35].

All the measurement of the IGM temperature in the literature assumed CDM cosmology. Because of the existing degeneracy between the IGM temperature and WDM, the assumption of the WDM cosmology could change the deduced values of the IGM temperature. Nevertheless, in the absence of such measurements, we compare our estimates for the IGM temperature with the measurements based on the CDM assumption.

The IGM temperature at z < 5 is constrained relatively well to be at the level T₀ ≥ (8–10) × 10⁴ K [25,22,27,28]. At z = 6.0 there is a single measurement, [29], that restricts T₀ to the range 5000 < T₀ < 10000 K (68% CL) (see e.g. [1] for discussion). The simplest interpretation of these data (also adopted in [1]) is that the temperature is growing monotonically with redshift. Instead, given the large error bars of the measurements, and taking into account adiabatic cooling one may expect a drop of temperature at z ∼ 5 with a subsequent rise to ~ 10⁴ K at z ∼ 4.6 in agreement with other measurements from [25,22,27,28]. This increase in IGM temperature can be explained with an early start of HeII reionization predicted by some models of reionization by quasars, [36] (see recent discussion of such “two-component” reionization models in [37]).

In such a scenario, the temperature at 5 < z < 6 depends on how long the first stage of reionization lasted and what the temperature of IGM was at z ≥ 6. As mentioned above, the measurement [29] at z ∼ 6 has large uncertainties. Theoretically, T₀(z = 6) depends on how early the first stage of hydrogen (and HeII) reion-

---

2 The temperature values that we have estimated at high redshift could be inaccurate, because the lowest temperature in the simulation grid was 5400 K.
5. Conclusion and future work

We demonstrated that the cut-off in the flux power spectrum, observed in the high resolution Lyman-α forest data may either be due to free-streaming of dark matter particles or be explained by the temperature of the intergalactic medium. Taking into account measurements at redshifts $z \sim 6$ and at $z \ll 5$ we see that if dark matter is warm, this requires non-monotonic dependence on the IGM temperature on $z$ with the local minimum at $z \sim 5.0-5.4$. Even cold dark matter slightly prefers a non-monotonic $T_0(z)$. Improving our knowledge of the IGM temperature at $z \sim 5-6$ will therefore either result in very strong Lyman-α bounds on DM free-streaming, essentially excluding its influence on observable small-scale structures, or (if temperature will be found to be well below 5000 K) would lead to the discovery of WDM.

A method that would allow to measure the IGM temperature at the redshifts of interest was presented in [16]. It is based on the following idea: for high resolution spectra it is not necessary to study average deviation from the QSO continuum per redshift bins (as it is done in lower resolution case) but it is possible to identify individual absorption lines and to measure their broadening. The thermal Doppler effect broadens the natural lorentzian line profile of the Lyman-α transition proportionally to the square root of the temperature, and one would like to use this information to determine the temperature of the IGM directly. However, there are other effects that contribute to the line width – the physical extent and the clustering of the underlying filaments. The method of [16] potentially allows to disentangle these effects. In view of our results it is important to attempt to apply this method to observational data. This is a method that has been tested with simulations at redshift $\sim 3$, and it still has to be seen if it works at redshift 5.

Acknowledgements

The authors are grateful to Matteo Viel, for sharing with them the code used in [1], and making this analysis possible. The authors thank James Bolton, Joop Schaye and Tom Thoms for useful discussions on the IGM temperature at high redshift. AG thanks Mark Lovell for sharing his knowledge about generating SN power spectra. She also thanks Bin Hu, Samuel Leach, Matteo Martinelli and Jesus Torrado for useful discussions on MCMC method. The authors thank the anonymous referee for his helpful comments, that improved the manuscript by large extent. The research was supported in part by the European Research Council under the European Union’s Seventh Framework Programme (FP7/2007–2013)/ERC grant agreements 278594-GasAroundGalaxies.

\[ 10^6 (n_e - n_\gamma)/s \] (see [50] for details) the linear power can be colder than that of thermal relics with $m_{\text{WDM}} = 2.1$ keV (Fig. 6), thus being fully admissible by the data.\(^3\) Notice that the non-resonant sterile neutrino dark matter with a 7 keV mass would be excluded at more than 3$\sigma$ level by previous constraints from the SDSS [7,6].
