Let $P$ be a set of $n$ points in the plane. We consider the problem of partitioning $P$ into two subsets $P_1$ and $P_2$ such that the sum of the perimeters of $CH(P_1)$ and $CH(P_2)$ is minimized, where $CH(P_i)$ denotes the convex hull of $P_i$. The problem was first studied by Mitchell and Wynters in 1991 who gave an $O(n^2)$ time algorithm. Despite considerable progress on related problems, no subquadratic time algorithm for this problem was found so far. We present an exact algorithm solving the problem in $O(n \log^4 n)$ time and a $(1 + \varepsilon)$-approximation algorithm running in $O(n + 1/\varepsilon^2 \cdot \log^4(1/\varepsilon))$ time.
There are many possible variants of the bipartition problem on planar point sets, which differ in how the cost of a clustering is defined. A variant that received a lot of attention is the 2-center problem [8, 11, 12, 15, 20], where the cost of a partition \((P_1, P_2)\) of the given point set \(P\) is defined as the maximum of the radii of the smallest enclosing disks of \(P_1\) and \(P_2\). Other cost functions that have been studied include the maximum diameter of the two point sets [3] and the sum of the diameters [14]; see also the survey by Agarwal and Sharir [2] for some more variants.

A natural class of cost function considers the size of the convex hulls \(\text{CH}(P_1)\) and \(\text{CH}(P_2)\) of the two subsets, where the size of \(\text{CH}(P_i)\) can either be defined as the area of \(\text{CH}(P_i)\) or as the perimeter \(\text{per}(P_i)\) of \(\text{CH}(P_i)\). (The perimeter of \(\text{CH}(P_i)\) is the length of the boundary \(\partial \text{CH}(P_i)\).) This class of cost functions was already studied in 1991 by Mitchell and Wynters [17]. They studied four problem variants: minimize the sum of the perimeters, the maximum of the perimeters, the sum of the areas, or the maximum of the areas. In three of the four variants the convex hulls \(\text{CH}(P_1)\) and \(\text{CH}(P_2)\) in an optimal solution may intersect [17, full version] – only in the minimum perimeter-sum problem the optimal bipartition is guaranteed to be a so-called line partition, that is, a solution with disjoint convex hulls. For each of the four variants they gave an \(O(n^3)\) algorithm that uses \(O(n)\) storage and that computes computes an optimal line partition; for all except the minimum area-maximum problem they also gave an \(O(n^2)\) algorithm that uses \(O(n^2)\) storage. Note that (only) for the minimum perimeter-sum problem the computed solution is an optimal bipartition. Around the same time, the minimum-perimeter sum problem was studied for partitions into \(k\) subsets for \(k > 2\); for this variant Capoyleas et al. [7] presented an algorithm with running time \(O(n^{6k})\). Mitchell and Wynters mentioned the improvement of the space requirement of the quadratic-time algorithm as an open problem, and they stated the existence of a subquadratic algorithm for any of the four variants as the most prominent open problem.

Rokne et al. [18] made progress on the first question, by presenting an \(O(n^2 \log n)\) algorithm that uses only \(O(n)\) space for the line-partition version of each of the four problems. Devillers and Katz [10] gave algorithms for the min-max variant of the problem, both for area and perimeter, which run in \(O((n + k) \log^2 n)\) time. Here \(k\) is a parameter that is only known to be in \(O(n^2)\), although Devillers and Katz suspected that \(k\) is subquadratic. They also gave linear-time algorithms for these problems when the point set \(P\) is in convex position and given in cyclic order. Segal [19] proved an \(\Omega(n \log n)\) lower bound for the min-max problems. Very recently, and apparently unaware of some of the earlier work on these problems, Bae et al. [4] presented an \(O(n^2 \log n)\) time algorithm for the minimum-perimeter-sum problem and an \(O(n^4 \log n)\) time algorithm for the minimum-area-sum problem (considering all partitions, not only line partitions). Despite these efforts, the main question is still open: is it possible to obtain a subquadratic algorithm for any of the four bipartition problems based on convex-hull size?

### 1.1 Our contribution

We answer the question above affirmatively by presenting a subquadratic algorithm for the minimum perimeter-sum bipartition problem in the plane.

As mentioned, an optimal solution \((P_1, P_2)\) to the minimum perimeter-sum bipartition problem must be a line partition. A straightforward algorithm would generate all \(\Theta(n^2)\) line partitions and compute the value \(\text{per}(P_1) + \text{per}(P_2)\) for each of them. If the latter is done from scratch for each partition, the resulting algorithm runs in \(O(n^3 \log n)\) time. The algorithms by Mitchell and Wynters [17] and Rokne et al. [18] improve on this by using that the different
line bipartitions can be generated in an ordered way, such that subsequent line partitions differ in at most one point. Thus the convex hulls do not have to be recomputed from scratch, but they can be obtained by updating the convex hulls of the previous bipartition. To obtain a subquadratic algorithm a fundamentally new approach is necessary: we need a strategy that generates a subquadratic number of candidate partitions, instead considering all line partitions. We achieve this as follows.

We start by proving that an optimal bipartition \((P_1, P_2)\) has the following property:

- either there is a set of \(O(1)\) canonical orientations such that \(P_1\) can be separated from \(P_2\) by a line with a canonical orientation, or
- the distance between \(\text{ch}(P_1)\) and \(\text{ch}(P_2)\) is at least \(\Omega(\min(\text{per}(P_1), \text{per}(P_2)))\).

There are only \(O(1)\) bipartitions of the former type, and finding the best among them is relatively easy. The bipartitions of the second type are much more challenging. We show how to employ a compressed quadtree to generate a collection of \(O(n)\) canonical 5-gons – intersections of axis-parallel rectangles and canonical halfplanes – such that the smaller of \(\text{ch}(P_1)\) and \(\text{ch}(P_2)\) (in a bipartition of the second type) is contained in one of the 5-gons.

It then remains to find the best among the bipartitions of the second type. Even though the number of such bipartitions is linear, we cannot afford to compute their perimeters from scratch. We therefore design a data structure to quickly compute \(\text{per}(P \setminus Q)\), where \(Q\) is a query canonical 5-gon. Brass et al. [6] presented such a data structure for the case where \(Q\) is an axis-parallel rectangle. Their structure uses \(O(n \log^2 n)\) space and has \(O(\log^7 n)\) query time; it can be extended to handle canonical 5-gons as queries, at the cost of increasing the space usage to \(O(n \log^3 n)\) and the query time to \(O(\log^7 n)\). Our data structure improves upon this: it has \(O(\log^4 n)\) query time for canonical 5-gons (and \(O(\log^3 n)\) for rectangles) while using the same amount of space. Using this data structure to find the best bipartition of the second type we obtain our main result: an exact algorithm for the minimum perimeter-sum bipartition problem that runs in \(O(n \log^4 n)\) time. As our model of computation we use the real RAM (with the capability of taking square roots) so that we can compute the exact perimeter of a convex polygon – this is necessary to compare the costs of two competing clusterings. We furthermore make the (standard) assumption that the model of computation allows us to compute a compressed quadtree of \(n\) points in \(O(n \log n)\) time; see footnote 2 on page 10.

Besides our exact algorithm, we present a linear-time \((1 + \varepsilon)\)-approximation algorithm. Its running time is \(O(n + T(1/\varepsilon^2)) = O(n + 1/\varepsilon^2 \cdot \log^4(1/\varepsilon))\), where \(T(1/\varepsilon^2)\) is the running time of an exact algorithm on an instance of size \(1/\varepsilon^2\).

Some arguments are omitted due to limited space. See the full version [1] for the details.

## 2 The exact algorithm

In this section we present an exact algorithm for the minimum-perimeter-sum partition problem. We first prove a separation property that an optimal solution must satisfy, and then we show how to use this property to develop a fast algorithm.

Let \(P\) be the set of \(n\) points in the plane for which we want to solve the minimum-perimeter-sum partition problem. An optimal partition \((P_1, P_2)\) of \(P\) has the following two basic properties: \(P_1\) and \(P_2\) are non-empty, and the convex hulls \(\text{ch}(P_1)\) and \(\text{ch}(P_2)\) are disjoint [17, full version]. In the remainder, whenever we talk about a partition of \(P\), we refer to a partition with these two properties.
2.1 Geometric properties of an optimal partition

Consider a partition \((P_1, P_2)\) of \(P\). Define \(P_1 := \text{CH}(P_1)\) and \(P_2 := \text{CH}(P_2)\) to be the convex hulls of \(P_1\) and \(P_2\), respectively, and let \(\ell_1\) and \(\ell_2\) be the two inner common tangents of \(P_1\) and \(P_2\). The lines \(\ell_1\) and \(\ell_2\) define four wedges: one containing \(P_1\), one containing \(P_2\), and two empty wedges. We call the opening angle of the empty wedges the separation angle of \(P_1\) and \(P_2\). Furthermore, we call the distance between \(P_1\) and \(P_2\) the separation distance of \(P_1\) and \(P_2\).

\[\textbf{Theorem 1.}\ \text{Let } P \text{ be a set of } n \text{ points in the plane, and let } (P_1, P_2) \text{ be a partition of } P \text{ that minimizes } \text{per}(P_1) + \text{per}(P_2). \text{ Then the separation angle of } P_1 \text{ and } P_2 \text{ is at least } \pi/6 \text{ or the separation distance is at least } c_{\text{sep}} \cdot \min(\text{per}(P_1), \text{per}(P_2)), \text{ where } c_{\text{sep}} := 1/250.\]

The remainder of this section is devoted to proving Theorem 1. To this end let \((P_1, P_2)\) be a partition of \(P\) that minimizes \(\text{per}(P_1) + \text{per}(P_2)\). Let \(\ell_3\) and \(\ell_4\) be the outer common tangents of \(P_1\) and \(P_2\). We define \(\alpha\) to be the angle between \(\ell_3\) and \(\ell_4\). More precisely, if \(\ell_3\) and \(\ell_4\) are parallel we define \(\alpha := 0\), otherwise we define \(\alpha\) as the opening angle of the wedge defined by \(\ell_3\) and \(\ell_4\) containing \(P_1\) and \(P_2\). We denote the separation angle of \(P_1\) and \(P_2\) by \(\beta\); see Fig. 1.

The idea of the proof is as follows. Suppose that the separation distance and the separation angle \(\beta\) are both relatively small. Then the region \(A\) in between \(P_1\) and \(P_2\) and bounded from the bottom by \(\ell_3\) and from the top by \(\ell_4\) is relatively narrow. But then the left and right parts of \(\partial A\) (which are contained in \(\partial P_1\) and \(\partial P_2\)) would be longer than the bottom and top parts of \(\partial A\) (which are contained in \(\ell_3\) and \(\ell_4\)), thus contradicting that \((P_1, P_2)\) is an optimal partition. To make this idea precise, we first prove that if the separation angle \(\beta\) is small, then the angle \(\alpha\) between \(\ell_3\) and \(\ell_4\) must be large. Second, we show that there is a value \(f(\alpha)\) such that the distance between \(P_1\) and \(P_2\) is at least \(f(\alpha) \cdot \min(\text{per}(P_1), \text{per}(P_2))\). Finally we argue that this implies that if the separation angle is smaller than \(\pi/6\), then (to avoid the contradiction mentioned above) the separation distance must be relatively large. Next we present our proof in detail.

Let \(c_{ij}\) be the intersection point between \(\ell_i\) and \(\ell_j\), where \(i < j\). If \(\ell_3\) and \(\ell_4\) are parallel, we choose \(c_{34}\) as a point at infinity on \(\ell_3\). Assume without loss of generality that neither \(\ell_1\) nor \(\ell_2\) separate \(P_1\) from \(c_{34}\), and that \(\ell_3\) is the outer common tangent such that \(P_1\) and \(P_2\) are to the left of \(\ell_3\) when traversing \(\ell_3\) from \(c_{34}\) to an intersection point in \(\ell_3 \cap P_1\). Assume furthermore that \(c_{13}\) is closer to \(c_{34}\) than \(c_{23}\).

For two lines, rays, or segments \(r_1, r_2\), let \(\angle(r_1, r_2)\) be the angle we need to rotate \(r_1\) in counterclockwise direction until \(r_1\) and \(r_2\) are parallel. For three points \(a, b, c\), let \(\angle(a, b, c) := \angle(ba, bc)\). For \(i = 1, 2\) and \(j = 1, 2, 3, 4\), let \(s_{ij}\) be a point in \(P_i \cap \ell_j\). Let \(\partial P_i\) denote the boundary of \(P_i\) and \(\text{per}(P_i)\) the perimeter of \(P_i\). Furthermore, let \(\partial P_i(x, y)\) denote the portion of \(\partial P_i\) from \(x \in \partial P_i\) counterclockwise to \(y \in \partial P_i\), and \(\text{length}(\partial P_i(x, y))\) denote the length of \(\partial P_i(x, y)\).
Lemma 2. We have $\alpha + 3\beta \geq \pi$.

Proof. Since $\text{per}(P_1) + \text{per}(P_2)$ is minimum, we know that
\[
\text{length}(\partial P_1(s_{13}, s_{14})) + \text{length}(\partial P_2(s_{24}, s_{23})) \leq \Psi,
\]
where $\Psi := |s_{13}s_{23}| + |s_{14}s_{24}|$. Furthermore, we know that $s_{11}, s_{12} \in \partial P_1(s_{13}, s_{14})$ and $s_{21}, s_{22} \in \partial P_2(s_{24}, s_{23})$. We thus have
\[
\text{length}(\partial P_1(s_{13}, s_{14})) + \text{length}(\partial P_2(s_{24}, s_{23})) \geq \Phi,
\]
where $\Phi := |s_{13}s_{11}| + |s_{11}s_{12}| + |s_{12}s_{14}| + |s_{24}s_{21}| + |s_{21}s_{22}| + |s_{22}s_{23}|$. Hence, we must have
\[
\Phi \leq \Psi. \tag{1}
\]

Now assume that $\alpha + 3\beta < \pi$. We will show that this assumption, together with inequality (1), leads to a contradiction, thus proving the lemma. To this end we will argue that if (1) holds, then it must also hold when (i) $s_{21}$ or $s_{22}$ coincides with $c_{12}$, and (ii) $s_{11}$ or $s_{12}$ coincides with $c_{12}$. To finish the proof it then suffices to observe that if (i) and (ii) hold, then $P_1$ and $P_2$ touch in $c_{12}$ and so (1) contradicts the triangle inequality.

It remains to argue that if (1) holds, then we can create a situation where (1) holds and (i) and (ii) hold as well. To this end we ignore that the points $s_{ij}$ are specific points in the set $P$ and allow the point $s_{ij}$ to move on the tangent $\ell_j$, as long as the movement preserves (1). Moving $s_{13}$ along $\ell_1$ away from $s_{23}$ increases $\Psi$ more than it increases $\Phi$, so (1) is preserved. Similarly, we can move $s_{14}$ away from $s_{24}$, $s_{23}$ away from $s_{13}$, and $s_{24}$ away from $s_{14}$.

We first show how to create a situation where (i) holds, and (1) still holds as well. Let $\gamma_j := \angle(\ell_i, \ell_j)$. We consider two cases.

Case (A): $\gamma_{32} < \pi - \beta$.

Note that $\angle(xs_{23}, \ell_2) \geq \gamma_{32}$ for any $x \in s_{22}c_{12}$. However, by moving $s_{23}$ sufficiently far away we can make $\angle(xs_{23}, \ell_2)$ arbitrarily close to $\gamma_{32}$, and we can ensure that $\angle(xs_{23}, \ell_2) < \pi - \beta$ for any point $x \in s_{22}c_{12}$. We now let the point $x$ move at unit speed from $s_{22}$ towards $c_{12}$. To be more precise, let $T := |s_{22}c_{12}|$, let $v$ be the unit vector with direction from $c_{23}$ to $c_{12}$, and for any $t \in [0, T]$ define $x(t) := s_{22} + t \cdot v$. Note that $x(0) = s_{22}$ and $x(T) = c_{12}$.

Let $a(t) := |x(t)s_{23}|$ and $b(t) := |x(t)s_{21}|$. In the full version [1] we show that
\[
a'(t) = -\cos(\angle(x(t)s_{23}, \ell_2)) \quad \text{and} \quad b'(t) = \cos(\angle(\ell_2, x(t)s_{21})).
\]

Since $\angle(x(t)s_{23}, \ell_2) < \pi - \beta$ for any value $t \in [0, T]$, we get $a'(t) < -\cos(\pi - \beta)$. Furthermore, we have $\angle(\ell_2, x(t)s_{21}) \geq \pi - \beta$ and hence $b'(t) \leq \cos(\pi - \beta)$. Therefore, $a'(t) + b'(t) < 0$ for any $t$ and we conclude that $a(T) + b(T) \leq a(0) + b(0)$. This is the same as $|s_{21}c_{12}| + |c_{12}s_{23}| \leq |s_{21}s_{22}| + |s_{22}s_{23}|$, so (1) still holds when we substitute $s_{22}$ by $c_{12}$.

Case (B): $\gamma_{32} \geq \pi - \beta$.

Using our assumption $\alpha + 3\beta < \pi$ we get $\gamma_{32} > \alpha + 2\beta$. Note that $\gamma_{14} = \pi - \gamma_{32} + \alpha + \beta$. Hence, $\gamma_{14} < \pi - \beta$. By moving $s_{24}$ and $s_{21}$, we can in a similar way as in Case (A) argue that (1) still holds when we substitute $s_{21}$ by $c_{12}$.

We conclude that in both cases we can ensure (i) without violating (1).

Since $\gamma_{42} \leq \gamma_{32}$ and $\gamma_{13} \leq \gamma_{14}$, we likewise have $\gamma_{42} < \pi - \beta$ or $\gamma_{13} < \pi - \beta$. Hence, we can substitute $s_{11}$ or $s_{12}$ by $c_{12}$ without violating (1), thus ensuring (ii) and finishing the proof. \qed
Let \( \text{dist}(P_1, P_2) := \min_{(p,q) \in P_1 \times P_2} |pq| \) denote the separation distance between \( P_1 \) and \( P_2 \). Recall that \( \alpha \) denotes the angle between the two common outer tangents of \( P_1 \) and \( P_2 \); see Fig. 1.

\[ \text{dist}(P_1, P_2) \geq f(\alpha) \cdot \text{per}(P_1), \]  

where \( f: [0, \pi] \rightarrow \mathbb{R} \) is the increasing function

\[ f(\varphi) := \frac{\sin(\varphi/4)}{1 + \sin(\varphi/2)} \cdot \frac{\sin(\varphi/2)}{1 + \sin(\varphi/2)} \cdot \frac{1 - \cos(\varphi/4)}{2}. \]

**Proof.** The statement is trivial if \( \alpha = 0 \) so assume \( \alpha > 0 \). Let \( p \in P_1 \) and \( q \in P_2 \) be points so that \( |pq| = \text{dist}(P_1, P_2) \) and assume without loss of generality that \( pq \) is a horizontal segment with \( p \) being its left endpoint. Let \( \ell_{1}^{\text{vert}} \) and \( \ell_{2}^{\text{vert}} \) be vertical lines containing \( p \) and \( q \), respectively. Note that \( P_1 \) is in the closed half-plane to the left of \( \ell_{1}^{\text{vert}} \) and \( P_2 \) is in the closed half-plane to the right of \( \ell_{2}^{\text{vert}} \). Recall that \( s_{ij} \) denotes a point on \( \partial P_i \cap \ell_j \).

**Claim 4.** There exist two convex polygons \( P_1' \) and \( P_2' \) satisfying the following conditions:

1. \( P_1' \) and \( P_2' \) have the same outer common tangents as \( P_1 \) and \( P_2 \), namely \( \ell_3 \) and \( \ell_4 \).
2. \( P_1' \) is to the left of \( \ell_1^{\text{vert}} \) and \( p \in \partial P_1' \); and \( P_2' \) is to the right of \( \ell_2^{\text{vert}} \) and \( q \in \partial P_2' \).
3. \( \text{per}(P_1') = \text{per}(P_1) \).
4. \( \text{per}(P_1') + \text{per}(P_2') \leq \text{per}(\text{cut}(P_1' \cup P_2')) \).
5. There are points \( s_{ij} \in P_i' \cap \ell_j \) for all \( i \in \{1, 2\} \) and \( j \in \{3, 4\} \) such that \( \partial P_1'(s_{13}', p) \), \( \partial P_1'(p, s_{14}') \), \( \partial P_2'(s_{24}', q) \), and \( \partial P_2'(q, s_{23}') \) each consist of a single line segment.
6. Let \( s_{2j}'(\lambda) := s_{2j}' - (\lambda, 0) \) and let \( \ell_{ij}'(\lambda) \) be the line through \( s_{ij}' \) and \( s_{2j}'(\lambda) \) for \( j \in \{3, 4\} \). Then \( \angle(\ell_{ij}'(pq), \ell_{ij}'(pq')) \geq \alpha/2 \).

**Proof of the Claim.** Let \( P_1' := P_1 \) and \( P_2' := P_2 \), and let \( s_{ij}' \) be a point in \( P_i' \cap \ell_j \) for all \( i \in \{1, 2\} \) and \( j \in \{3, 4\} \). We show how to modify \( P_1' \) and \( P_2' \) until they have all the required conditions. Of course, they already satisfy conditions 1–4. We first show how to obtain condition 5, namely that \( \partial P_1'(s_{13}', p) \) and \( \partial P_1'(p, s_{14}') \) – and similarly \( \partial P_2'(s_{24}', q) \) and...
We modify \(\delta\) where \(\delta\) and let conditions 5 and 6. Consider what happens if we move \(P\) and condition 6 is satisfied. However, if the slopes of \(\ell,\ell\) condition 5 is now satisfied.

The only condition that \((P_1', P_2')\) might not satisfy is condition 6. Let \(s_{2j}'(\lambda) := s_{2j}' - (\lambda, 0)\) and let \(\ell_j(\lambda)\) be the line through \(s_{2j}'(\lambda)\) and \(s_{1j}'\) for \(j \in \{3, 4\}\). Clearly, if the slopes of \(\ell_3\) and \(\ell_4\) have different signs (as in Fig. 2), the angle \(\angle(\ell_3(\lambda),\ell_4(\lambda))\) is increasing for \(\lambda \in [0, |pq|]\), and condition 6 is satisfied. However, if the slopes of \(\ell_3\) and \(\ell_4\) have the same sign, the angle might decrease.

Consider the case where both slopes are positive — the other case is analogous. Changing \(P_2'\) by substituting \(\partial P_2'(s_{23}', s_{24}')\) with the line segment \(s_{23}'s_{24}'\) makes \(\text{per}(P_1') + \text{per}(P_2')\) and \(\text{per}(\text{ch}(P_1' \cup P_2'))\) decrease equally much and hence condition 4 is preserved. This clearly has no influence on the other conditions. We thus assume that \(P_2'\) is the triangle \(qs_{23}'s_{24}'\). Consider what happens if we move \(s_{23}'\) along the line \(\ell_3\) away from \(c_{34}\) with unit speed. Then \(|s_{13}s_{23}'|\) grows with speed exactly 1 whereas \(|qs_{23}'|\) grows with speed at most 1. We therefore preserve condition 4, and the other conditions are likewise not affected.

We now move \(s_{23}'\) sufficiently far away so that \(\angle(\ell_3, \ell_4(|pq|)) \leq \alpha / 4\). Similarly, we move \(s_{24}'\) sufficiently far away from \(c_{34}\) along \(\ell_4\) to ensure that \(\angle(\ell_4, \ell_4(|pq|)) \leq \alpha / 4\). It then follows that \(\angle(\ell_3(|pq|), \ell_4(|pq|)) \geq \angle(\ell_3, \ell_4) - \alpha / 2 = \alpha / 2\), and condition 6 is satisfied.

Note that condition 2 in the claim implies that \(\text{dist}(P_1', P_2') = \text{dist}(P_1, P_2) = |pq|\), and hence inequality (2) follows from condition 3 if we manage to prove \(\text{dist}(P_1', P_2') \geq f(\alpha) \cdot \text{per}(P_1')\). Therefore, with a slight abuse of notation, we assume from now on that \(P_1\) and \(P_2\) satisfy the conditions in the claim, where the points \(s_{ij}\) play the role as \(s_{ij}'\) in conditions 5 and 6.

We now consider a copy of \(P_2\) that is translated horizontally to the left over a distance \(\lambda\); see Fig. 2. Let \(s_{24}(\lambda), s_{23}(\lambda),\) and \(q(\lambda)\) be the translated copies of \(s_{24}, s_{23},\) and \(q\), respectively, and let \(\ell_j(\lambda)\) be the line through \(s_{1j}\) and \(s_{2j}(\lambda)\) for \(j \in \{3, 4\}\). Furthermore, define

\[
\Phi(\lambda) := [s_{13}p] + [s_{14}p] + [s_{23}(\lambda)q(\lambda)] + [s_{24}(\lambda)q(\lambda)]
\]

and

\[
\Psi(\lambda) := [s_{13}s_{23}(\lambda)] + [s_{14}s_{24}(\lambda)].
\]

Note that \(\Phi(\lambda) = \Phi\) is constant. By conditions 4 and 5, we know that

\[
\Phi \leq \Psi(0). \tag{3}
\]

Note that \(q(|pq|) = p\). In the full version [1] we show that

\[
\Phi - \Psi(|pq|) \geq \sin(\delta / 2) \cdot \frac{1 - \cos(\delta / 2)}{1 + \sin(\delta / 2)} \cdot (|s_{13}p| + |s_{14}p|), \tag{4}
\]

where \(\delta := \angle(\ell_3(|pq|), \ell_4(|pq|))\). By condition 6, we know that \(\delta \geq \alpha / 2\). The function \(\delta \mapsto \sin(\delta / 2) \cdot \frac{1 - \cos(\delta / 2)}{1 + \sin(\delta / 2)}\) is increasing for \(\delta \in [0, \pi]\) and hence inequality (4) also holds for \(\delta = \alpha / 2\).
When $\lambda$ increases from 0 to $|pq|$ with unit speed, the value $\Psi(\lambda)$ decreases with speed at most $2$, i.e., $\Psi(\lambda) \geq \Psi(0) - 2\lambda$. Using this and inequalities (3) and (4), we get

$$2|pq| \geq \Psi(0) - \Psi(|pq|) \geq \Phi - \Phi + \sin(\alpha/4) \cdot \frac{1 - \cos(\alpha/4)}{1 + \sin(\alpha/4)} \cdot (|s_{13}p| + |s_{14}p|),$$

and we conclude that

$$|pq| \geq \frac{1}{2} \sin(\alpha/4) \cdot \frac{1 - \cos(\alpha/4)}{1 + \sin(\alpha/4)} \cdot (|s_{13}p| + |s_{14}p|). \quad (5)$$

By the triangle inequality, $|s_{13}p| + |s_{14}p| \geq |s_{13}s_{14}|$. Furthermore, for a given length of $s_{13}s_{14}$, the fraction $|s_{13}s_{14}|/(|s_{14}c_{34}| + |c_{34}s_{13}|)$ is minimized when $s_{13}s_{14}$ is perpendicular to the angular bisector of $\ell_3$ and $\ell_4$. (Recall that $c_{34}$ is the intersection point of the outer common tangents $\ell_3$ and $\ell_4$; see Fig. 2.) Hence

$$|s_{13}s_{14}| \geq \sin(\alpha/2) \cdot (|s_{14}c_{34}| + |c_{34}s_{13}|). \quad (6)$$

We now conclude

$$|s_{13}p| + |s_{14}p| = \frac{\sin(\alpha/2)}{1 + \sin(\alpha/2)} \cdot \left(\frac{|s_{13}p| + |s_{14}p|}{\sin(\alpha/2)} + |s_{13}p| + |s_{14}p|\right)$$

$$\geq \frac{\sin(\alpha/2)}{1 + \sin(\alpha/2)} \cdot \left(\frac{|s_{13}s_{14}|}{\sin(\alpha/2)} + |s_{13}p| + |s_{14}p|\right) \quad \text{by the triangle inequality}$$

$$\geq \frac{\sin(\alpha/2)}{1 + \sin(\alpha/2)} \cdot \left(|s_{14}c_{34}| + |c_{34}s_{13}| + |s_{13}p| + |s_{14}p|\right) \quad \text{by } (6)$$

$$\geq \frac{\sin(\alpha/2)}{1 + \sin(\alpha/2)} \cdot \text{per}(P_1),$$

where the last inequality follows because $P_1$ is fully contained in the quadrilateral $s_{14}, c_{34}, x_{13}, p$. The statement (2) in the lemma now follows from (5).

We are now ready to prove Theorem 1.

**Proof of Theorem 1.** If the separation angle of $P_1$ and $P_2$ is at least $\pi/6$, we are done. Otherwise, Lemma 2 gives that $\alpha > \pi/2$, and Lemma 3 gives that $\text{dist}(P_1, P_2) \geq f(\pi/2) \cdot \text{per}(P_1) \geq (1/250) \cdot \min(\text{per}(P_1), \text{per}(P_2))$. \hfill $\blacksquare$

### 2.2 The algorithm

Theorem 1 suggests to distinguish two cases when computing an optimal partition: the case where the separation angle is large (namely at least $\pi/6$) and the case where the separation distance is large (namely at least $c_{\text{sep}} \cdot \min(\text{per}(P_1), \text{per}(P_2))$). As we will see, the first case can be handled in $O(n \log n)$ time and the second case in $O(n \log^4 n)$ time, leading to the following theorem.

**Theorem 5.** Let $P$ be a set of $n$ points in the plane. Then we can compute a partition $(P_1, P_2)$ of $P$ that minimizes $\text{per}(P_1) + \text{per}(P_2)$ in $O(n \log^4 n)$ time using $O(n \log^3 n)$ space.

To find the best partition when the separation angle is at least $\pi/6$, we observe that in this case there is a separating line whose orientation is $j \cdot \pi/7$ for some $0 \leq j < 7$. For each of these orientations we can scan over the points with a line $\ell$ of the given orientation, and maintain the perimeters of the convex hulls on both sides. This takes $O(n \log n)$ time in total; see the full version [1].

Next we show how to compute the best partition with large separation distance. We assume without loss of generality that $\text{per}(P_2) \leq \text{per}(P_1)$. It will be convenient to treat the case where $P_2$ is a singleton separately.
Lemma 6. The point \( p \in P \) minimizing \( \text{per}(P \setminus \{p\}) \) can be computed in \( O(n \log n) \) time.

Proof. The point \( p \) we are looking for must be a vertex of \( \text{ch}(P) \). First we compute \( \text{ch}(P) \) in \( O(n \log n) \) time [5]. Let \( v_0, v_1, \ldots, v_{m-1} \) denote the vertices of \( \text{ch}(P) \) in counterclockwise order. Let \( \Delta_i \) be the triangle with vertices \( v_{i-1}v_iv_{i+1} \) (with indices taken modulo \( m \)) and let \( P_i \) denote the set of points lying inside \( \Delta_i \), excluding \( v_i \) but including \( v_{i-1} \) and \( v_{i+1} \). Note that any point \( p \in P \) is present in at most two sets \( P_i \). Hence, \( \sum_{i=0}^{m-1} |P_i| = O(n) \). It is not hard to compute the sets \( P_i \) in \( O(n \log n) \) time in total. After doing so, we compute all convex hulls \( \text{ch}(P_i) \) in \( O(n \log n) \) time in total. Since

\[
\text{per}(P \setminus \{v_i\}) = \text{per}(P) - |v_i - v_i| - |v_{i+1} - v_{i+1}| + \text{per}(P_i) - |v_{i-1} - v_{i+1}|,
\]

we can now find the point \( p \) minimizing \( \text{per}(P \setminus \{p\}) \) in \( O(n) \) time.

It remains to compute the best partition \((P_1, P_2)\) with \( \text{per}(P_2) \leq \text{per}(P_1) \) whose separation distance is at least \( c_{\text{sep}} \cdot \text{per}(P_2) \) and where \( P_2 \) is not a singleton. Let \((P_1^*, P_2^*)\) denote this partition. Define the size of a square\(^1\) \( \sigma \) to be its edge length. A square \( \sigma \) is a good square if (i) \( P_2^* \subset \sigma \), and (ii) \( \text{size}(\sigma) \leq c^* \cdot \text{per}(P_2^*) \), where \( c^* := 18 \). Our algorithm globally works as follows.

1. Compute a set \( S \) of \( O(n) \) squares such that \( S \) contains a good square.
2. For each square \( \sigma \in S \), construct a set \( H_\sigma \) of \( O(1) \) halfplanes such that the following holds: if \( \sigma \in S \) is a good square then there is a halfplane \( h \in H_\sigma \) such that \( P_2^* = P(\sigma \cap h) \), where \( P(\sigma \cap h) := P \cap (\sigma \cap h) \).
3. For each pair \((\sigma, h)\) with \( \sigma \in S \) and \( h \in H_\sigma \), compute \( \text{per}(P \setminus P(\sigma \cap h)) + \text{per}(P(\sigma \cap h)) \), and report the partition \((P \setminus P(\sigma \cap h), P(\sigma \cap h))\) that gives the smallest sum.

Step 1: Finding a good square. To find a set \( S \) that contains a good square, we first construct a set \( S_{\text{base}} \) of so-called base squares. The set \( S \) will then be obtained by expanding the base squares appropriately.

We define a base square \( \sigma \) to be good if (i) \( \sigma \) contains at least one point from \( P_2^* \), and (ii) \( c_1 \cdot \text{diam}(P_2^*) \leq \text{size}(\sigma) \leq c_2 \cdot \text{diam}(P_2^*) \), where \( c_1 := 1/4 \) and \( c_2 := 4 \) and \( \text{diam}(P_2^*) \) denotes the diameter of \( P_2^* \). Note that \( 2 \cdot \text{diam}(P_2^*) \leq \text{per}(P_2^*) \leq 4 \cdot \text{diam}(P_2^*) \). For a square \( \sigma \), define \( \overline{\sigma} \) to be the square with the same center as \( \sigma \) and whose size is \((1 + 2/c_1) \cdot \text{size}(\sigma)\).

Lemma 7. If \( \sigma \) is a good base square then \( \overline{\sigma} \) is a good square.

Proof. The distance from any point in \( \sigma \) to the boundary of \( \overline{\sigma} \) is at least

\[
\frac{\text{size}(\overline{\sigma}) - \text{size}(\sigma)}{2} \geq \text{diam}(P_2^*).
\]

Since \( \sigma \) contains a point from \( P_2^* \), it follows that \( P_2^* \subset \overline{\sigma} \). Since \( \text{size}(\sigma) \leq c_2 \cdot \text{diam}(P_2^*) \), we have

\[
\text{size}(\overline{\sigma}) \leq (2/c_1 + 1) \cdot c_2 \cdot \text{diam}(P_2^*) = 36 \cdot \text{diam}(P_2^*) \leq c^* \cdot \text{per}(P_2^*). \]

To obtain \( S \) it thus suffices to construct a set \( S_{\text{base}} \) that contains a good base square. To this end we first build a compressed quadtree for \( P \). For completeness we briefly review the definition of compressed quadtrees; see also Fig. 3 (left).

\(^1\) Whenever we speak of squares, we always mean axis-parallel squares.
Figure 3 A compressed quadtree and some of the base squares generated from it. In the right figure, only the points are shown that are relevant for the shown base squares.

Assume without loss of generality that $P$ lies in the interior of the unit square $U := [0, 1]^2$. Define a **canonical square** to be any square that can be obtained by subdividing $U$ recursively into quadrants. A **compressed quadtree** [13] for $P$ is a hierarchical subdivision of $U$, defined as follows. In a generic step of the recursive process we are given a canonical square $\sigma$ and the set $P(\sigma) := P \cap \sigma$ of points inside $\sigma$. (Initially $\sigma = U$ and $P(\sigma) = P$.)

- If $|P(\sigma)| \leq 1$ then the recursive process stops and $\sigma$ is a square in the final subdivision.
- Otherwise there are two cases. Consider the four quadrants of $\sigma$. The first case is that at least two of these quadrants contain points from $P(\sigma)$. (We consider the quadrants to be closed on the left and bottom side, and open on the right and top side, so a point is contained in a unique quadrant.) In this case we partition $\sigma$ into its four quadrants – we call this a **quadtree split** – and recurse on each quadrant. The second case is that all points from $P(\sigma)$ lie inside the same quadrant. In this case we compute the smallest canonical square, $\sigma'$, that contains $P(\sigma)$ and we partition $\sigma$ into two regions: the square $\sigma'$ and the so-called **donut region** $\sigma \setminus \sigma'$. We call this a **shrinking step**. After a shrinking step we only recurse on the square $\sigma'$, not on the donut region.

A compressed quadtree for a set of $n$ points can be computed in $O(n \log n)$ time in the appropriate model of computation\(^2\) [13]. The idea is now as follows. Let $p, p' \in P^*_2$ be a pair of points defining $\text{diam}(P^*_2)$. The compressed quadtree hopefully allows us to zoom in until we have a square in the compressed quadtree that contains $p$ or $p'$ and whose size is roughly equal to $|pp'|$. Such a square will be then a good base square. Unfortunately this does not always work since $p$ and $p'$ can be separated too early. We therefore have to proceed more carefully: we need to add five types of base squares to $S_{\text{base}}$, as explained next and illustrated in Fig. 3 (right).

**(B1)** Any square $\sigma$ that is generated during the recursive construction – note that this not only refers to squares in the final subdivision – is put into $S_{\text{base}}$.

**(B2)** For each point $p \in P$ we add a square $\sigma_p$ to $S_{\text{base}}$, as follows. Let $\sigma$ be the square of the final subdivision that contains $p$. Then $\sigma_p$ is a smallest square that contains $p$ and that shares a corner with $\sigma$.

---

\(^2\) In particular we need to be able to compute the smallest canonical square containing two given points in $O(1)$ time. See the book by Har-Peled [13] for a discussion.
(B3) For each square $\sigma$ that results from a shrinking step we add an extra square $\sigma'$ to $S_{\text{base}}$, where $\sigma'$ is the smallest square that contains $\sigma$ and that shares a corner with the parent square of $\sigma$.

(B4) For any two regions in the final subdivision that touch each other – we also consider two regions to touch if they only share a vertex – we add at most one square to $S_{\text{base}}$, as follows. If one of the regions is an empty square, we do not add anything for this pair. Otherwise we have three cases.

(B4.1) If both regions are non-empty squares containing points $p$ and $p'$, respectively, then we add a smallest enclosing square for the pair of points $p, p'$ to $S_{\text{base}}$.

(B4.2) If both regions are donut regions, say $\sigma_1 \setminus \sigma'_1$ and $\sigma_2 \setminus \sigma'_2$, then we add a smallest enclosing square for the pair $\sigma'_1, \sigma'_2$ to $S_{\text{base}}$.

(B4.3) If one region is a non-empty square containing a point $p$ and the other is a donut region $\sigma \setminus \sigma'$, then we add a smallest enclosing square for the pair $p, \sigma'$ to $S_{\text{base}}$.

Lemma 8. The set $S_{\text{base}}$ has size $O(n)$ and contains a good base square. Furthermore, $S_{\text{base}}$ can be computed in $O(n \log n)$ time.

Proof. A compressed quadtree has size $O(n)$ so we have $O(n)$ base squares of type (B1) and (B3). Obviously there are $O(n)$ base squares of type (B2). Finally, the number of pairs of final regions that touch is $O(n)$ – this follows because we have a planar rectilinear subdivision of total complexity $O(n)$ – and so the number of base squares of type (B4) is $O(n)$ as well. The fact that we can compute $S_{\text{base}}$ in $O(n \log n)$ time follows directly from the fact that we can compute the compressed quadtree in $O(n \log n)$ time [13].

It remains to prove that $S_{\text{base}}$ contains a good base square. We call a square $\sigma$ too small when $\text{size}(\sigma) < c_1 \cdot \text{diam}(P^*_2)$ and too large when $\text{size}(\sigma) > c_2 \cdot \text{diam}(P^*_2)$; otherwise we say that $\sigma$ has the correct size. Let $p, p' \in P^*_2$ be two points with $|pp'| = \text{diam}(P^*_2)$, and consider a smallest square $\sigma_{p,p'}$, in the compressed quadtree that contains both $p$ and $p'$. Note that $\sigma_{p,p'}$ cannot be too small, since $c_1 = 1/4 < 1/\sqrt{2}$. If $\sigma_{p,p'}$ has the correct size, then we are done since it is a good base square of type (B1). So now suppose $\sigma_{p,p'}$ is too large.

Let $\sigma_0, \sigma_1, \ldots, \sigma_k$ be the sequence of squares in the recursive subdivision of $\sigma_{p,p'}$ that contain $p$; thus $\sigma_0 = \sigma_{p,p'}$ and $\sigma_k$ is a square in the final subdivision. Define $\sigma'_0, \sigma'_1, \ldots, \sigma'_{k'}$, similarly, but now for $p'$ instead of $p$. Suppose that none of these squares has the correct size – otherwise we have a good base square of type (B1). There are three cases.

Case (i): $\sigma_k$ and $\sigma'_{k'}$ are too large.

We claim that $\sigma_k$ touches $\sigma'_{k'}$. To see this, assume without loss of generality that $\text{size}(\sigma_k) < \text{size}(\sigma'_{k'})$. If $\sigma_k$ does not touch $\sigma'_{k'}$ then $|pp'| > \text{size}(\sigma_k)$, which contradicts that $\sigma_k$ is too large. Hence, $\sigma_k$ indeed touches $\sigma'_{k'}$. But then we have a base square of type (B4.1) for the pair $p, p'$ and since $|pp'| = \text{diam}(P^*_2)$ this is a good base square.

Case (ii): $\sigma_k$ and $\sigma'_{k'}$ are too small.

In this case there are indices $0 < j \leq k$ and $0 < j' \leq k'$ such that $\sigma_{j-1}$ and $\sigma'_{j'-1}$ are too large and $\sigma_j$ and $\sigma'_{j'}$ are too small. Note that this implies that both $\sigma_j$ and $\sigma'_{j'}$ result from a shrinking step, because $c_1 < c_2/2$ and so the quadrants of a too-large square cannot be too small. We claim that $\sigma_{j-1}$ touches $\sigma'_{j'-1}$. Indeed, similarly to Case (i), if $\sigma_{j-1}$ and $\sigma'_{j'-1}$ do not touch then $|pp'| > \min(\text{size}(\sigma_{j-1}), \text{size}(\sigma'_{j'-1}))$, contradicting that both $\sigma_{j-1}$ and $\sigma'_{j'-1}$ are too large. We now have two subcases.

The first subcase is that the donut region $\sigma_{j-1} \setminus \sigma_j$ touches the donut region $\sigma'_{j'-1} \setminus \sigma'_{j'}$. Thus a smallest enclosing square for $\sigma_j$ and $\sigma'_{j'}$ has been put into $S_{\text{base}}$ as a base square of type (B4.2). Let $\sigma^*$ denote this square. Since the segment $pp'$ is contained
Lemma 9. \(\sigma^\ast\) \(\triangleq\) desired.

of two disjoint portions \(\sigma\) \(c\) \(\triangleq\) Moreover, \(\text{size}(P)\) \(\triangleq\) In the case where \(\text{size}(\sigma)\) \(\triangleq\) \(\text{size}(\sigma) + \text{size}(\sigma') + |pp'| \leq 3 \cdot \text{diam}(P_2^*) < c_2 \cdot \text{diam}(P^*_2)\),

and so \(\sigma^\ast\) \(\triangleq\) a good base square.

The second subcase is that \(\sigma_{j-1} \setminus \sigma_j\) does not touch \(\sigma'_{j-1} \setminus \sigma'_{j}\). This can only happen if \(\sigma_{j-1}\) and \(\sigma'_{j-1}\) just share a single corner, \(v\). Observe that \(\sigma_j\) must lie in the quadrant of \(\sigma_{j-1}\) that has \(v\) as a corner, otherwise \(|pp'| \geq \text{size}(\sigma_{j-1})/2\) and \(\sigma_{j-1}\) would not be too large. Similarly, \(\sigma'_{j}\) must lie in the quadrant of \(\sigma'_{j-1}\) that has \(v\) as a corner. Thus the base squares of type (B3) for \(\sigma_j\) and \(\sigma'_{j}\), both have \(v\) as a corner. Take the largest of these two base squares, say \(\sigma_j\). For this square \(\sigma^\ast\) we have

\[
c_1 \cdot \text{diam}(P_2^*) < \frac{\text{diam}(P_2^*)}{2\sqrt{2}} = \frac{|pp'|}{2\sqrt{2}} \leq \text{size}(\sigma^\ast),
\]

since \(|pp'|\) is contained in a square of twice the size of \(\sigma^\ast\). Furthermore, since \(\sigma_j\) is too small and \(|pv| < |pp'|\) we have

\[
\text{size}(\sigma^\ast) \leq \text{size}(\sigma_j) + |pv| \leq (c_1 + 1) \cdot \text{diam}(P_2^*) < c_2 \cdot \text{diam}(P^*_2).
\]

Hence, \(\sigma^\ast\) is a good base square.

Case (iii): neither (i) nor (ii) applies.

In this case \(\sigma_k\) is too small and \(\sigma'_{k'}\) is too large (or vice versa). Thus there must be an index \(0 < j \leq k\) such that \(\sigma_{j-1}\) is too large and \(\sigma_j\) is too small. We can now follow a similar reasoning as in Case (ii): First we argue that \(\sigma_j\) must have resulted from a shrinking step and that \(\sigma_{j-1}\) touches \(\sigma'_{j'}\). Then we distinguish two subcases, namely where the donut region \(\sigma_j \setminus \sigma_{j-1}\) touches \(\sigma'_{j'}\) and where it does not touch \(\sigma'_{j'}\). The arguments for the two subcases are similar to the subcases in Case (ii), with the following modifications. In the first subcase we use base squares of type (B4.3) and in (7) the term \(\text{size}(\sigma'_{j'})\) disappears; in the second subcase we use a type (B3) base square for \(\sigma_j\) and a type (B2) base square for \(p'\), and when the base square for \(p'\) is larger than the base square for \(\sigma_j\) then (8) becomes \(\text{size}(\sigma^\ast) \leq 2|p'v| < c_2 \cdot \text{diam}(P^*_2)\). \(\blacktriangleright\)

**Step 2: Generating halfplanes.** Consider a good square \(\sigma \in S\). Let \(Q_\sigma\) be a set of \(4 \cdot c^*/c_{\text{sep}} + 1 = 18001\) points placed equidistantly around the boundary of \(\sigma\). Note that the distance between two neighbouring points in \(Q_\sigma\) is less than \(c_{\text{sep}}/c^* \cdot \text{size}(\sigma)\). For each pair \(q_1, q_2\) of points in \(Q_\sigma\), add to \(H_\sigma\) the two halfplanes defined by the line through \(q_1\) and \(q_2\).

Lemma 9. For any good square \(\sigma \in S\), there is a halfplane \(h \in H_\sigma\) such that \(P_2^* = P(\sigma \cap h)\).

**Proof.** In the case where \(\sigma \cap P_1^* = \emptyset\), two points in \(Q_\sigma\) from the same edge of \(\sigma\) define a half-plane \(h\) such that \(P_2^* = P(\sigma \cap h)\), so assume that \(\sigma\) contains one or more points from \(P_1^*\).

We know that the separation distance between \(P_1^*\) and \(P_2^*\) is at least \(c_{\text{sep}} \cdot \text{per}(P_2^*)\). Moreover, \(\text{size}(\sigma) \leq c^* \cdot \text{per}(P_2^*)\). Hence, there is an empty open strip \(O\) with a width of at least \(c_{\text{sep}}/c^* \cdot \text{size}(\sigma)\) separating \(P_2^*\) from \(P_1^*\). Since \(\sigma\) contains a point from \(P_1^*\), we know that \(\sigma \setminus O\) consists of two pieces and that the part of the boundary of \(\sigma\) inside \(O\) consists of two disjoint portions \(B_1\) and \(B_2\) each of length at least \(c_{\text{sep}}/c^* \cdot \text{size}(\sigma)\). Hence the sets \(B_1 \cap Q_\sigma\) and \(B_2 \cap Q_\sigma\) contain points \(q_1\) and \(q_2\), respectively, that define a half-plane \(h\) as desired. \(\blacktriangleright\)
Step 3: Evaluating candidate solutions. In this step we need to compute for each pair \((\sigma, h)\) with \(\sigma \in S\) and \(h \in H_\sigma\), the value \(\text{per}(P \setminus P(\sigma \cap h)) + \text{per}(P(\sigma \cap h))\). We do this by preprocessing \(P\) into a data structure that allows us to quickly compute \(\text{per}(P \setminus P(\sigma \cap h))\) and \(\text{per}(P(\sigma \cap h))\) for a given pair \((\sigma, h)\). Recall that the bounding lines of the halfplanes \(h\) we must process have \(O(1)\) different orientations. We construct a separate data structure for each orientation.

Consider a fixed orientation \(\phi\). We build a data structure \(D_\phi\) for range searching on \(P\) with ranges of the form \(\sigma \cap h\), where \(\sigma\) is a square and \(h\) is halfplane whose bounding line has orientation \(\phi\). Since the edges of \(\sigma\) are axis-parallel and the bounding line of the halfplanes \(h\) have a fixed orientation, we can use a standard three-level range tree [5] for this. Constructing this tree takes \(O(n \log^2 n)\) time and the tree has \(O(n \log^2 n)\) nodes.

Each node \(\nu\) of the third-level trees in \(D_\phi\) is associated with a canonical subset \(P(\nu)\), which contains the points stored in the subtree rooted at \(\nu\). We preprocess each canonical subset \(P(\nu)\) as follows. First we compute the convex hull \(\text{CH}(P(\nu))\). Let \(v_1, \ldots, v_k\) denote the convex-hull vertices in counterclockwise order. We store these vertices in order in an array, and we store for each vertex \(v_i\) the value \(\text{length}(\partial P(v_i, v_i))\), that is, the length of the part of \(\partial \text{CH}(P(\nu))\) from \(v_1\) to \(v_i\) in counterclockwise order. Note that the convex hull \(\text{CH}(P(\nu))\) can be computed in \(O(|P(\nu)|)\) from the convex hulls at the two children of \(\nu\). Hence, the convex hulls \(\text{CH}(P(\nu))\) (and the values \(\text{length}(\partial P(v_i, v_i))\)) can be computed in \(\sum_{\nu \in D_\phi} O(|P(\nu)|) = O(n \log^2 n)\) time in total, in a bottom-up manner.

Now suppose we want to compute \(\text{per}(P(\sigma \cap h))\), where the orientation of the bounding line of \(h\) is \(\phi\). We perform a range query in \(D_\phi\) to find a set \(N(\sigma \cap h)\) of \(O(\log^2 n)\) nodes such that \(P(\sigma \cap h)\) is equal to the union of the canonical subsets of the nodes in \(N(\sigma \cap h)\). Standard range-tree properties guarantee that the convex hulls \(\text{CH}(P(\nu))\) and \(\text{CH}(P(\mu))\) of any two nodes \(\nu, \mu \in N(\sigma \cap h)\) are disjoint. Note that \(\text{CH}(P(\sigma \cap h))\) is equal to the convex hull of the set of convex hulls \(\text{CH}(P(\nu))\) with \(\nu \in N(\sigma \cap h)\). In the full version [1] we show that we can compute \(\text{per}(P(\sigma \cap h))\) in \(O(\log^4 n)\) time.

Observe that \(P \setminus P(\sigma \cap h)\) can also be expressed as the union of \(O(\log^3 n)\) canonical subsets with disjoint convex hulls, since \(\mathbb{R}^2 \setminus (\sigma \cap h)\) is the disjoint union of \(O(1)\) ranges of the right type. Hence, we can compute \(\text{per}(P \setminus P(\sigma \cap h))\) in \(O(\log^4 n)\) time. We thus obtain the following result, which finishes the proof of Theorem 5.

**Lemma 10.** Step 3 can be performed in \(O(n \log^4 n)\) time and using \(O(n \log^3 n)\) space.

3. The approximation algorithm

**Theorem 11.** Let \(P\) be a set of \(n\) points in the plane and let \((P_1^*, P_2^*)\) be a partition of \(P\) minimizing \(\text{per}(P_1^*) + \text{per}(P_2^*)\). Suppose we have an exact algorithm for the minimum perimeter-sum problem running in \(T(k)\) time for instances with \(k\) points. Then for any given \(\varepsilon > 0\) we can compute a partition \((P_1, P_2)\) of \(P\) such that \(\text{per}(P_1) + \text{per}(P_2) \leq (1 + \varepsilon) \cdot (\text{per}(P_1^*) + \text{per}(P_2^*))\) in \(O(n + T(1/\varepsilon^2))\) time.

**Proof.** Consider the axis-parallel bounding box \(B\) of \(P\). Let \(w\) be the width of \(B\) and let \(h\) be its height. Assume without loss of generality that \(w \geq h\). Our algorithm works in two steps.

**Step 1:** Check if \(\text{per}(P_1^*) + \text{per}(P_2^*) \leq w/16\). If so, compute the exact solution.

We partition \(B\) vertically into four strips with width \(w/4\), denoted \(B_1, B_2, B_3,\) and \(B_4\) from left to right. If \(B_2\) or \(B_3\) contains a point from \(P\), we have \(\text{per}(P_1^*) + \text{per}(P_2^*) \geq w/2 > w/16\) and we go to Step 2. If \(B_2\) and \(B_3\) are both empty, we consider two cases.
Case (i): $h \leq w/8$. In this case we simply return the partition $(P \cap B_1, P \cap B_4)$. To see that this is optimal, we first note that any subset $P' \subset P$ that contains a point from $B_1$ as well as a point from $B_4$ has $\per(P') \geq 2 \cdot (3w/4) = 3w/2$. On the other hand, $\per(P \cap B_1) + \per(P \cap B_4) \leq 2 \cdot (w/2 + 2h) \leq 3w/2$.

Case (ii): $h > w/8$. We partition $B$ horizontally into four rows with height $h/4$, numbered $R_1, R_2, R_3$, and $R_4$ from bottom to top. If $R_2$ or $R_3$ contains a point from $P$, we have $\per(P_1^* \setminus \pi) + \per(P_2^* \setminus \pi) \geq h/2 > w/16$, and we go the Step 2. If $R_2$ and $R_3$ are both empty, we overlay the vertical and the horizontal partitioning of $B$ to get a $4 \times 4$ grid of cells $C_{ij} := B_i \cap R_j$ for $i, j \in \{1, \ldots, 4\}$. We know that only the corner cells $C_{11}, C_{14}, C_{41}, C_{44}$ contain points from $P$. If three or four corner cells are non-empty, $\per(P_1^* \setminus \pi) + \per(P_2^* \setminus \pi) \geq 6h/4 > w/16$. Hence, we may without loss of generality assume that any point of $P$ is in $C_{11}$ or $C_{44}$. We now return the partition $(P \cap C_{11}, P \cap C_{44})$, which is easily seen to be optimal.

Step 2: Handle the case where $\per(P_1^*) + \per(P_2^*) > w/16$.

The idea is to compute a subset $\hat{P} \subset P$ of size $O(1/\varepsilon^2)$ such that an exact solution to the minimum perimeter-sum problem on $\hat{P}$ can be used to obtain a $(1 + \varepsilon)$-approximation for the problem on $P$.

We subdivide $B$ into $O(1/\varepsilon^2)$ rectangular cells of width and height at most $c := \varepsilon w/(64\pi \sqrt{2})$. For each cell $C$ where $P \cap C$ is non-empty we pick an arbitrary point in $P \cap C$, and we let $\hat{P}$ be the set of selected points. For a point $p \in \hat{P}$, let $C(p)$ be the cell containing $p$. Intuitively, each point $p \in \hat{P}$ represents all the points $P \cap C(p)$. Let $(\hat{P}_1, \hat{P}_2)$ be a partition of $\hat{P}$ that minimizes $\per(\hat{P}_1) + \per(\hat{P}_2)$. We assume we have an algorithm that can compute such an optimal partition in $T(|\hat{P}|)$ time. For $i = 1, 2$, define

$$P_i := \bigcup_{p \in \hat{P}_i} P \cap C(p).$$

Our approximation algorithm returns the partition $(P_1, P_2)$. (Note that the convex hulls of $P_1$ and $P_2$ are not necessarily disjoint.) It remains to prove the approximation ratio.

First, note that $\per(\hat{P}_1) + \per(\hat{P}_2) \leq \per(P_1^*) + \per(P_2^*)$ since $\hat{P} \subseteq P$. For $i = 1, 2$, let $\hat{P}_i$ consist of all points in the plane (not only points in $P$) within a distance of at most $\sqrt{2}c$ from $\Ch(\hat{P}_i)$. In other words, $\hat{P}_i$ is the Minkowskii sum of $\Ch(\hat{P}_i)$ with a disk $D$ of radius $c\sqrt{2}$ centered at the origin. Note that if $p \in \hat{P}_1$, then $q \in \hat{P}_2$ for any $q \in P \cap C(p)$, since any two points in $C(p)$ are at most $\sqrt{2}c$ apart from each other. Therefore $P_1 \subseteq \hat{P}_1$ and hence $\per(P_1) \leq \per(P_1)$. Note also that $\per(P_1) = \per(P_1) + 2\pi \sqrt{2}$. These observations yield

$$\per(P_1) + \per(P_2) \leq \per(\hat{P}_1) + \per(\hat{P}_2) = \per(P_1^*) + \per(P_2^*) + 4\pi \sqrt{2} \leq \per(P_1^*) + \per(P_2^*) + 4\pi \sqrt{2}.$$

As all the steps can be done in linear time, the time complexity of the algorithm is $O(n + T(n_\varepsilon))$ for some $n_\varepsilon = O(1/\varepsilon^2)$.
