**Abstract**

**Background:** DNA methylation plays a key role in the regulation of gene expression and carcinogenesis. Bisulfite sequencing studies mainly focus on calling single nucleotide polymorphism, different methylation region, and find allele-specific DNA methylation. Until now, only a few software tools have focused on virus integration using bisulfite sequencing data. **Findings:** We have developed a new and easy-to-use software tool, named BS-virus-finder (BSVF,
DNA methylation plays a crucial role in many areas including development [1, 2] and X chromosome inactivation [3] by regulating genetic imprinting and epigenetic modification without altering DNA sequences. Previous studies have shown a strong association of DNA methylation with cancer. The methylation status altering related to carcinogenesis [4], cancer recurrence [5], and metastasis [6] has already been revealed by emerging bisulfite sequencing (BS) technology. BS technology can investigate DNA methylation changes with single-base accuracy. Treatment of DNA with bisulfite converts unmethylated cytosine residues to uracil, but leaves 5-methylcytosine residues unmodified [7]. Thus, bisulfite treatment introduces specific changes in the DNA sequence that depend on the methylation status of individual cytosine residues, yielding single-nucleotide resolution information about the methylation status of a segment of DNA (Fig. 1). Various analyses can be performed on the altered sequences to retrieve this information. BS technology can reveal differences between cytosines and thymidine and sequence change resulting from bisulfite conversion. For the bases without methylation, all Cs will change to Ts on both strands. After directional library preparation, we have 2 different conversions: the Watson and the Crick strands, as shown in Fig. 1. On the

**Introduction**

**Figure 1:** The illustration of bisulfite-altered sequence to the original.
Description of in silico and real data

Different types of paired-end (PE) reads (50 base pairs [bp], 90 bp, 150 bp) that include 700 breakpoints in chromosome 1 (chr 1) of GRCh38 were simulated in our study. Input fragments of 50 to 400 bp were randomly selected from chr 1 in the GRCh38 assembly of the human genome. The hepatitis B virus (HBV) genome (GenBank: X04615.1) was used in our simulation. Its integration length was between 45 bp and 180 bp. We cut HBV-containing segments with given PE insert size at all possible positions on every integration event. After alignment, mapping accuracy of each of the 17 different types of read mappings was calculated (Fig. 2). Mapping accuracy varied among the 17 types of read mappings in our simulation (Figs S1, S2, S3). In summary, the accuracies of several kinds of the read mappings were low (Tables S1, S2, S3), which may raise the false-negative rate. Generally, however, bwa-meth [12] performed very well.

Bisulfite sequencing is a sophisticated technique to study DNA cytosine methylation. Bisulfite treatment followed by polymerase chain reaction (PCR) amplification specifically converts unmethylated cytosine to thymine. By cooperating with next-generation sequencing technology, it is able to detect the methylation status of every cytosine in the whole genome. Moreover, longer reads make it possible to achieve higher accuracy. Besides simulated data, the PLC/PRF/5 hepatocellular carcinoma cell lines (from American Type Culture Collection [ATCC], Manassas, VA, USA) were cultured as previously described [19]. The cell line was validated by STR makers (Fig. S4). We performed whole-genome sequencing (WGS) and WGBS sequencing of this cell line (the results are shown in Table S4). Table 1 shows the analysis result for WGS data, which were compared with the output results analyzed by Vy-per [20], virus-clip [21], and Virus Finder2 [22].

Methods

Sample preparation

PLC/PRF/5 hepatocellular carcinoma cell line was obtained from ATCC (Manassas, VA, USA) and was cultured as previously described [19] and validated by STR makers (Fig. S4). In total, 15 μg of DNA was extracted to perform WGS and WGBS sequencing. Sample concentration was detected by fluorometer (Qubit-Fluorometer, Invitrogen). Sample integrity and purification was determined by Agarose Gel Electrophoresis.

Whole-genome sequencing

About 1.5 μg of gDNA was sonicated to 100–300-bp fragment genome DNA by Sonication (Covaris) and purified with QIAquick PCR Purification Kit (Qiagen). Adapter ligation and target insert size fragment recovering and quantifying library by real-time

BSVF used WGBS data, and other software used WGS data.

*Supported by previous fluorescence in situ hybridization (FISH) experiments [8].

Abbreviations: HB: host breakpoint; VB: virus begin is the revealed leftmost position on virus; VE: virus end is the rightmost position on virus.

Quantitative PCR (QPCR; TaqMan Probe) were then performed. The qualified library was sequenced on an Illumina HiSeq X Ten platform, and 150 bp of PE reads were obtained. In total, around 90 G of clean data were generated.

**Whole-genome bisulfite sequencing**

About 3 μg of gDNA were sonicated to 100–300 bp by Sonication (Covaris) and purified with MiniElute PCR Purification Kit (QIAGEN). A single “A” nucleotide was added to the 3’ ends of the blunt fragments. Methylated adapters were then purified and added to the 5’ and 3’ ends of each strand in the genomic fragment. Sizes 300–400 bp were selected. DNA was then purified with QIAquick Gel Extraction Kit (QIAGEN) and bisulfite treated with Methylation-Gold Kit (ZYMO). Finally, PCR was conducted and sizes 350–400 bp were selected and purified with QIAquick Gel Extraction kit (QIAGEN). Qualified library was amplified on cBot to generate the cluster on the flowcells (TruSeq PE Cluster Kit V3-cBot-HS, Illumina). The flowcells were sequenced for 150 bp of PE reads on the HiSeq X Ten platform, and more than 90 G of clean data were generated.

**Data analysis**

The read coverage situation for 1 integration is shown in Fig. 3. Four steps were implemented to detect virus integration:

1. **Alignment:** We use bwa-meth [12] to align bisulfite-treated sequencing reads to a hybrid reference that contains both human genome and virus sequences. For chimeric reads from the junction parts, BWA-MEM [23] will align it to 1 organism and mark the unmapped part as soft clipping, which is in fact from the other organism. This enables us to find breakpoints directly from the alignment.

2. **Clustering:** After alignment, the result was filtered. We select read pairs with 1 read match by the following criterion: The Phred-scaled mapping quality is larger than 30 (≥30), and at least 1 soft clipping is longer than 5 bp (≥5). The mapped parts of reads, which is marked as “M” by its CIGAR string, cover the human reference genome. For paired reads, we also add the gap between 2 mapped reads to their covered region, making read 1 and read 2 continuously covered on the human reference. Each continuous region with at least 1 bp of overlap is defined as a cluster. All reads involved are selected to form the cluster. The remaining soft clippings are viral junction candidates. Read pairs with 1 read mapped on the virus also indicate a potential virus junction between the read pairs.

3. **Assembling:** Within 1 cluster, all soft clipping start sites are collected. The position with the most abundance of start sites is identified as the most likely candidate breakpoint. All clipping sequences in the cluster are extracted and aligned together. A restore algorithm was used to calculate the most possible base in each position based on the aligned bases and their sequencing quality. The algorithm is based on a Bayesian model, where we compute the posterior probability estimation for A, C, G, T as:

\[
P(T_i|D) = \frac{P(T_{W})P(D|T_{W})}{\sum_{x=1}^{S} P(T_{Wx})P(D|T_{Wx})} \times \frac{P(T_{C})P(D|T_{C})}{\sum_{x=1}^{S} P(T_{Cx})P(D|T_{Cx})}
\]

\[
C_0 = \frac{\sum_{x=1}^{S} P(T_{W})P(D|T_{Wx})P(D|T_{Cx})}{\sum_{x=1}^{S} P(T_{Cx})P(D|T_{Cx})}
\]

Where \(T_i\) is the position of read length of the read and \(D\) is the mapped region of the genome.
Figure 3: A demo plot of 1 viral integration cluster in its pre-insertion form.

Here, D is the observation of the next-generation sequencing (NGS) reads on given position. \( P(T_i | D) \) is the likelihood component, which can be interpreted as the probability of observing D when the true genotype is \( T_i \). \( D_W \) is a realization (or observation) of the NGS reads in the Watson strand. \( P(T_W | D) \) is the likelihood component, which can be interpreted as the probability of observing D when the true genotype is \( T_W \). At each virus location, prior probability \( P(T_i) \) of each genotype \( T_i \) was set according to Table S5. The likelihood \( P(D | T_i) \) for the assumed genotype \( T_i \) was calculated from the observed allele types in the sequencing reads in formula 2. Thus, on the Watson strand, it is \( P(D_W | T_i) \), and on the Crick strand it is \( P(D_C | T_i) \). We defined the likelihood of observing allele \( d_k \) in a read for a possible haploid genotype \( T \) as \( P(d_k | T) \). So, for a set of n observed alleles at a locus, \( D = \{d_1, d_2, \ldots, d_n\} \) on each strand, these probabilities are computed as shown by formulas (3) and (4), where Q stands for the base quality from the fastaq file.

\[
P(D_W | T_i) = \prod_{k=1}^{m} P(d_{W_k} | T), \quad P(D_C | T_i) = \prod_{k=1}^{n} P(d_{C_k} | T). \tag{2}
\]

\[
P(d_{W_k} | T) = \begin{cases} 1 - 10^{-\frac{Q}{10}} & (T \in \{C, G, T\}) \\ 1 - 10^{-\frac{Q}{10}} \times \frac{1}{2} & (T \in \{A\}) \end{cases} \tag{3}
\]

\[
P(d_{C_k} | T) = \begin{cases} 1 - 10^{-\frac{Q}{10}} & (T \in \{C, G, T\}) \\ 1 - 10^{-\frac{Q}{10}} \times \frac{1}{2} & (T \in \{A\}) \end{cases} \tag{4}
\]

We used “Y” and “R” to represent C/T and G/A, respectively (IUPAC nucleotide code). If a region is covered by both the Watson strand and the Crick strand, we were able to deduce the original base from Y or R by calculation.

4. Detection of viral integrations: The assembled clipping regions above were mapped to the given virus reference sequence with a Smith-Waterman local alignment tool from the EMBOSS package [24], which supports IUPAC DNA codes Y and R. Virus fragment location is extracted from the alignment results.

Discussion

In summary, we have implemented the first software tool to detect virus integration using BS data. Our software is based on bwa-meth, and by assembling and aligning soft-clip regions, it can find the virus breakpoints. However, accuracy of reads surrounding the breakpoints needs to be further improved. A virus usually integrates into regions that are homologous to both human and virus (micro-homologous) [25]. Therefore, we consider breakpoints predicted by our software tool correctly identified if they are within 10 bp of a real breakpoint (Fig. S2). With this definition, the accuracy of our predicted breakpoints can reach over 70%. Our results will be useful for analyzing BS data and related applications. Some of the results come with only a location on human genome, and the virus location missing. This may be due to the shortage of virus fragments. We simulated 3 kinds of
reads, PE50, 90, and 150 with various lengths, and further simulated virus-inserted fragment with different lengths as well (Table S6); thus all cases described in Fig. 2 are mimicked here. All simulations sampled all possible reads, base by base with fixed insert sizes. As the result in Table S6 showed, the longer the reads, the more accurate a prediction can be achieved. In particular, for read lengths around 50 bp, BS-virus-finder is capable of finding the virus integration with an accuracy of more than 70%; for the read lengths between 90 bp and 150 bp, BS-virus-finder is capable of finding the virus integration with an accuracy of more than 90%. Apart from simulated data, we have performed WGS and WGBS sequencing of the PLC/PRF/5 hepatocellular carcinoma cell line (Table S4). As the results show, when the length of input is larger than 150 bp, the analysis result of WGBS is similar to the one of WGS. Additionally, BS-virus-finder is able to find breakpoints in 8 out of 9 regions identified by FISH [8]. Based on these experimental results, we believe that BS-virus-finder is a powerful software tool to analyze virus integration using BS data.

### Availability and requirements

**Project Name:** BS-virus-finder: virus integration calling using bisulfite-sequencing data  
**Project home page:** [https://github.com/BGI-SZ/BSVF](https://github.com/BGI-SZ/BSVF)  
**Operating system:** Linux  
**Programming language:** Perl, Python, C  
**License:** LGPL v3  
**Research Resource Identifier:** BSVF, RRID:SCR_015727

### Availability of supporting data

Data used in this paper are simulated based on random insertion of the HBV sequence into the human chromosome 1 sequence. A Perl script named "simVirusInserts.pl" is included, and our simulation schema is coded within. We have run the simulation several times, and the result shows no significant difference. The PLC/PRF/5 hepatocellular carcinoma cell lines were from American Type Culture Collection (ATCC, Manassas, VA, USA) and sequenced by HiSeq X Ten System from Novogene company. WGS and WGBA data have been submitted to NCBI SRA project PRJNA400455. Supporting data, an archival copy of the code, and the Perl script "simVirusInserts.pl" are also available via the GigaScience repository, GigaDB [27].
