Abstract

Background: Several chemical UV filters/absorbers ('UV filters' hereafter) have endocrine-disrupting properties *in vitro* and *in vivo*. Exposure to these chemicals, especially during prenatal development, is of concern.

Objectives: To examine maternal exposure to UV filters, associations with maternal thyroid hormone, with growth factor concentrations as well as to birth outcomes.

Methods: Prospective study of 183 pregnant women with 2nd trimester serum and urine samples available. Maternal concentrations of the chemical UV filters benzophenone-1 (BP-1) and benzophenone-3 (BP-3) in urine and 4-hydroxy-benzophenone (4-HBP) in serum were measured by liquid chromatography–tandem mass spectrometry (LC–MS/MS). The relationships between 2nd trimester maternal concentrations of the three chemical UV filters and maternal serum concentrations of thyroid hormones and growth factors, as well as birth outcomes (weight, height, and head and abdominal circumferences) were examined.

Results: Positive associations between maternal serum concentrations of 4-HBP and triiodothyronine (T₃), thyroxine (T₄), insulin-like growth factor I (IGF-I) and its binding protein IGFBP3 were observed in mothers carrying male fetuses. Male infants of mothers in the middle 4-HBP exposure group had statistically significantly lower weight and shorter head and abdominal circumferences at birth compared to the low exposure group.

Conclusions: Widespread exposure of pregnant women to chemical UV filters and the possible impact on maternal thyroid hormones and growth factors, and on fetal growth, calls for further studies on possible long-term consequences of the exposure to UV filters on fetal development and children's health.

Introduction

Several recent studies have shown that human exposure to chemicals used as UV filters/absorbers is prevalent (1, 2, 3, 4, 5). Exposure to UV filters occurs not only by intentional

use of sunscreens. Due to their ability to absorb UV light, UV filters are used as 'UV-absorbers' in a wide range of everyday products such as for protecting colors from

bleaching, plastic from becoming friable in the sunlight or as photo-initiators in ink (6, 7, 8, 9, 10, 11, 12). For practical reasons, we will refer to all of these chemicals as 'UV filters' throughout this paper, regardless of their use in industry. The widespread use of chemical UV filters results in human exposure throughout the year (2). The prevalent human exposure to UV filters is of concern as several of these chemicals have endocrine-disrupting properties demonstrated in *in vitro* animal and human studies (13, 14, 15, 16, 17, 18, 19, 20, 21). We recently investigated the concentrations of seven different chemical UV filters in maternal blood and urine, and in amniotic fluid, and found that the UV filters benzophenone-1 (BP-1), benzophenone-3 (BP-3) and 4-hydroxybenzophenone (4-HBP) were present in the majority of pregnant women (3). Although concentrations were significantly lower in amniotic fluid samples, BP-1 and BP-3 as well as 4-HBP could also be found in the cord blood of several of the participants, indicating that these compounds might also cross the placenta and reach the fetus.

Successful intrauterine development of the human fetus is highly dependent on hormonal regulation, and disturbance of hormones during pregnancy might therefore have dramatic consequences for the development of the unborn child. In humans, urinary concentrations of BP-3 was associated with decrease in thyroid hormones in both background population and pregnant women (22, 23) and when measured in urine of pregnant women, BP-3 was associated with sex-dependent impact on birthweight (decreased in girls and increased in boys) (5) and decreased gestational length in boys (24). In the present study, we examined the associations of 2nd trimester maternal concentrations of three prevalently present UV filters (BP-1, BP-3 in maternal urine and 4-HBP in maternal serum) to maternal serum concentrations of thyroid hormones and growth factors and also to birth outcomes.

Materials and methods

Study population and materials

The study population consisted of participants in a study on the distribution of UV filters in urine, serum and amniotic fluid and consisted of 200 pregnant women undergoing amniocentesis at either Copenhagen University Hospital Hvidovre or Rigshospitalet. The study has previously been described in detail (3); in short, blood, urine and amniotic fluid samples were collected simultaneously from each woman during the second trimester of pregnancy when they arrived at the hospital for the amniocentesis procedure

during the period September 2012 to August 2014. In the current study, only results measured from blood and urine are included. The indication for amniocentesis varied but largely the women could be divided into three groups according to the severity of the amniocentesis indication and outcome: group 1: women referred for amniocentesis solely because of maternal request and/or high maternal age and found to carry fetuses with normal karyotype and normal results of ultrasound scan; group 2 women with increased risk for neural tube defects (NTDs), intestinal atresia, trisomy 18 or 21 or unspecific echogenic bowl on ultrasound scan, but who were found to carry a fetus without any malformations and with a normal karyotype and group 3: women carrying a fetus with either malformations found by ultrasound scan or with an abnormal karyotype, or both.

Information on maternal prepregnancy BMI, sex of the fetus, gestational age at sampling and at birth and birth outcome measured at delivery were all obtained from medical records.

Among the 200 pregnant women included in the study, 15 were excluded from analyses for the following reasons: medication for thyroid disease ($n=4$), overtly pathological thyroid hormones at the time of sampling ($n=2$), missing BMI information ($n=6$) and missing infant sex information ($n=3$) resulting in a total of 185 pregnant women. Due to missing serum samples from two of them, only 183 pregnant women were included in the analyses for thyroid hormones and growth factors collected at amniocentesis (study group 1, Fig. 1). Furthermore, 22 of the women had an abortion after the samples were collected and in 6 additional cases all birth outcome data were missing, resulting in 157 mother-child pairs for the birth outcome analyses based on urine samples and 155 mother-child pairs based on serum samples (study group 2, Fig. 1). One hundred fifty-five of the mother-child pairs were included in both the analyses of maternal hormone concentrations and birth outcomes in relation to UV filter concentrations.

All participants signed a declaration of informed consent prior to sample collection. The study was approved by The Ethics Committee of the Capital Region of Denmark (H-2-2012-76) and by The Danish Data Protection Agency (2012-58-0004).

Hormone analyses

Maternal serum samples were stored at -20°C until analyzed in one batch in March 2016 for thyroid hormones and in March 2017 for growth factors, with

Figure 1
Study population and number of biological samples included in analyses on thyroid hormones and growth factors (study group 1) and in analyses on birth outcomes (study group 2). ¹Includes medication for thyroid disease (n=4) and overtly pathological thyroid hormones at the time of sampling (n=2).

the exception of two samples, which were analyzed for thyroid hormones in March 2017.

The thyroid hormones triiodothyronine (T₃), free triiodothyronine (fT₃), thyroxine (T₄) and free thyroxine (fT₄) were measured by competitive electrochemiluminescence immunoassays (ECLIA) and thyroid-stimulating hormone (TSH) by a sandwich electrochemiluminescence immunoassay (ECLIA) on a Cobas 8000, Modular e602 (Roche) at the Department of Clinical Biochemistry, Rigshospitalet, University of Copenhagen, Denmark. Interassay coefficients of variation were <8% for all thyroid hormone assays. Limit of detection was 0.014 U/L, 0.3 nmol/L, 1.5 pmol/L, 5.4 nmol/L, and 3 pmol/L for TSH, T₃, fT₃, T₄ and fT₄, respectively.

Analyzed growth factors included insulin-like growth factor I (IGF-I) and its major binding protein: insulin-like growth factor-binding protein-3 (IGFBP3). IGF-I and IGFBP3 were both measured by a chemiluminescence immunoassay on the IDS-iSYS automated platform (Immuno Diagnostic Systems, IDS) at the Hormone Laboratory of the Department of Growth and Reproduction, Rigshospitalet, Copenhagen University, Denmark. Interassay coefficient of variation and limit of detection were respectively <13% and below 80 µg/L for IGFBP3 and <8% and 10 µg/L for IGF-I.

Chemical analysis of UV filters

Maternal urine and serum samples were analyzed for seven different UV filters by isotope dilution TurboFlow-liquid chromatography–tandem mass spectrometry (LC–MS/MS) (25), and the measured concentrations have previously been reported in detail (3). In the present study, only the three UV filters, which were present at concentrations above detection limits in more than 60% of samples are included: benzophenone-1 (BP-1) and benzophenone-3 (BP-3) in maternal urine and 4-hydroxy-benzophenone (4-HBP) in maternal serum. The octanol/water partition coefficients (log K_{ow}) of these three benzophenones indicate that they are sufficiently hydrophilic to not bioaccumulate and urine is usually the preferred matrix for this kind of substances. However, we have previously shown that in paired urine and serum samples from this study population, 4-HBP was more frequently present in detectable concentrations in serum (88% of the samples) than in urine (21% of the samples) (3).

Adjustment for urinary dilution

In order to be able to adjust measured urinary concentrations of UV filters for the urinary dilution, the osmolality of the urine samples were measured by freezing point depression method with an automatic

cryoscopic osmometer (Osmomat 030 from Gonotec, Berlin, Germany). Urinary osmolality was chosen as an adjustment method for urinary dilution as it was shown to be less affected by other exogenous factors in comparison to other known methods (26). Measured urinary UV filter concentrations were osmolality adjusted to account for urinary dilution using the following equation:

$$C_{\text{corr}} = \frac{C_i \times \text{Osm}_{\text{ref}}}{\text{Osm}_{\text{meas}}}$$

where C_{corr} is the corrected concentration, C_i is the measured biomarker concentration, Osm_{meas} is the measured osmolality in the sample and Osm_{ref} is the reference osmolality value corresponding to the median osmolality of all the included urine samples (=0.376 osmol/kg).

Statistical analyses

Concentrations of UV filters below LOD were set to the respective LOD divided by square root of two. The associations between measured concentrations of urinary BP-1, BP-3 and serum 4-HBP in pregnant women at 2nd trimester and their serum concentrations of thyroid hormones, the growth factors IGF-I and IGFBP3 as well as the birth outcomes of their infants were examined by General Linear Models (GLM). The exposure biomarkers were entered individually in the models as either a continuous or a categorical independent variable: concentrations of BP-3 and 4-HBP were grouped into the low, medium and high exposure categories based on the tertiles. For BP-1, the fraction of samples with undetectable concentrations exceeded 33%, and for this compound, all undetectable samples were categorized to the low exposure group, while the rest of the samples were distributed equally into the medium and high exposure groups (for boundaries of the categories, Table 2). The distribution into low, medium and high exposure categories were made separately for models of associations with maternal thyroid hormones and growth factors and for models of association with birth outcomes because of a different number of samples included in the models of the different outcomes (Fig. 1).

Potential covariates in the study were maternal prepregnancy BMI (both as a continuous and a categorical (<20, 20–25, >25) variable), maternal smoking, parity, maternal age, maternal educational status, sex of the fetus and gestational age (either at time of sampling for models of associations with maternal hormones, or at birth for models of associations with birth outcomes) and season

(Summer=May–August, Winter=September–April) of sampling. The influence of the potential covariates was checked by including them in the GLM one by one. Sex and gestational age of the infant and maternal BMI had all influence on statistical significance, defined as P value below or above 0.05 of the final result of examined GLM. Gestational age at sampling and maternal prepregnancy BMI were entered as covariates in all analyses of the association with maternal hormones, while gestational age at birth and prepregnancy BMI were used as covariates in all analyses of the associations with birth outcomes. The impact of maternal prepregnancy BMI in the model was not linear and BMI was therefore included as a categorical variable (<20, 20–25 and >25). Furthermore, all analyses were stratified on the sex of the fetus because the concentrations of placental growth hormone (a major regulator of maternal IGF-I production during pregnancy) (27, 28) are known to be affected by fetal sex (29, 30), and birth outcomes in general are sex dimorphic (31).

In subsequent sensitivity analyses, we also included maternal smoking as a confounder in the full model of associations of the exposure biomarkers to birth outcomes because maternal smoking is well known to be associated with decreased birth weight (32). Likewise, in additional sensitivity analyses, we included season of sampling and season at birth as a confounder in the full model of associations of the exposure biomarkers to respectively maternal hormone concentrations and birth outcomes, showing that season did not have any significant impact on the results (data not shown).

Furthermore, as intrauterine growth retardation (IUGR) can be caused by several factors not related to endocrine factors, we repeated all analyses on birth outcome with exclusion of all IUGR pregnancies ($n=20$, IUGR defined according to the Danish national guideline as fetal weight below the 10th percentile for gestational age as determined through ultrasound) to see whether it changed the results of the final model.

Although UV filters concentrations were not normally distributed, transformation of the data was not necessary to achieve normal distribution and constant variance of the standardized residuals of GLM examined by visual inspection of the plots. All the statistical analyses described earlier were performed in IBM SPSS 22.

Due to the biological association between IGF-I and its binding protein IGFBP3, we calculated mediation proportion in order to examine whether observed associations of the exposure biomarkers to IGF-I were directly associated or possibly mediated through IGFBP3.

AC groups: Pregnancies stratified into three groups according to the severity of the indication for and outcome of the amniocentesis as described in the 'Materials and methods' section.

^aStatistical significant differences between the AC groups, *P*-value <0.05; ^bosmolality adjusted concentrations; ^cKruskal–Wallis test: Group 1 was significantly older than the other two groups; ^dKruskal–Wallis test: Gestational age at amniocentesis was significantly higher in group 3;

^eChi-square test; ^fChi-square test: Number of life born children was significantly lower in group 3; ^gKruskal–Wallis test; ^hKruskal–Wallis test: Serum concentrations of 4-HBP were significantly lower in group 1.

AC, amniocentesis; fT₃, free triiodothyronine; fT₄, free thyroxine; IGF-I, insulin-like growth factor I; IGFBP3, insulin-like growth factor binding protein 3; s4-HBP, serum 4-hydroxy benzophenone; T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid stimulating hormone; uBP-1, urinary benzophenone 1; uBP-3, urinary benzophenone 3.

Calculations of mediation proportions were performed in the lava-package (version 1.5.1 (33)) in the statistical software 'R' (version 3.3.2 (34)).

Results

Basic characteristics of the women included in the study are presented in Table 1 for the full study group and stratified by three amniocentesis (AC) subgroups

based on the severity of the indication and outcome of the amniocentesis as indicated in the 'Materials and methods' section. Women in AC subgroup 1 were older and had statistically significantly lower 4-HBP serum concentrations than the two other subgroups. Supplementary statistical analyses showed that maternal 4-HBP levels were associated with age (data not shown) and the difference in 4-HBP concentrations between the AC group 1 and the two other groups could be explained

Table 2 Distribution of second trimester maternal urinary (u) benzophenone-1 (BP-1) and benzophenone-3 (BP-3) concentrations^a (ng/mL) and serum (s) 4-hydroxy-benzophenone (4-HBP) concentrations (ng/mL).

UV filter	n > LOD (%)	LOD ^b	Min	Median	Exposure groups			Max

Stratification into exposure tertiles is based on study population 1 (n=183).

^aOsmolality adjusted concentrations; ^blimit of detection (ng/mL) for raw measurements before osmolality adjustment; ^cthe number of samples in the low exposure group to BP-1 exceeds the number of samples below LOD because four samples in the low exposure group to BP-1 were >LOD before osmolality adjustment but gave a value <0.25 (ng/mL) after osmolality adjustment.

by the difference in age. As the three subgroups did not differ significantly from each other on any of the other parameters studied, all subsequent analyses were done on the full study group.

The distribution of maternal urinary BP-1 and BP-3 concentrations and maternal serum 4-HBP concentrations in the three exposure groups used when modeling exposure as a categorical variable are shown in Table 2. Median and range of the birth outcomes of the infants, obtained from medical records, are shown in Table 3 stratified by sex of the child.

Associations between maternal UV filter concentrations and maternal thyroid hormones and growth factors

For maternal urinary BP-1 and BP-3 concentrations, no statistically significant associations (P values: >0.05) to maternal thyroid hormones, IGF-I or IGFBP3 were observed (data not shown).

For women carrying a male fetus, we observed significant positive associations between maternal serum 4-HBP concentrations and maternal T₃, T₄, IGF-I and IGFBP3 concentrations when adjusted for gestational age at sampling. These associations remained significant for IGF-I and IGFBP3 when additionally adjusted for prepregnancy BMI (Supplementary Table 1.1, see section on supplementary data given at the end of this article). The effect estimates indicated that an increase of 1 ng/mL in maternal 4-HBP serum concentrations was associated with an average increase in maternal serum concentrations of T₃ of 0.27 nmol/L (95% CI: 0.05–0.49, P=0.02) and T₄ of 11.9 nmol/L (95% CI: 0.66–23.0, P=0.04) when adjusted for gestational age at sampling, and an increase in IGF-I of 19 µg/L (95% CI: 1.4–37, P=0.04) and IGFBP3 of 516 µg/L (95% CI: 72.8–959, P=0.02) when adjusted for both gestational age and maternal prepregnancy BMI.

For women carrying a female fetus, no associations between maternal serum 4-HBP and maternal T₃ or T₄ were observed (Supplementary Table 1.2) but instead a significant negative association with maternal fT₄ concentrations was observed. The effect estimates indicate that an increase of 1 ng/mL in 4-HBP serum concentrations was associated with an average decrease of maternal fT₄ serum concentrations of 1 pmol/L (95% CI: –0.14 to –1.88), P=0.02). The associations between maternal serum 4-HBP and maternal growth factors were less pronounced for women carrying a female fetus, although a positive trend with serum IGFBP3 concentrations was still evident, with women in the highest exposure group having significantly higher IGFBP3 serum concentrations than women in the lowest exposure group (P=0.04). Effect estimates for the association between maternal serum 4-HBP and maternal serum IGFBP3 were of the same order as observed for women carrying a male fetus.

Serum IGF-I and IGFBP3 concentrations are known to be highly correlated (27) and in order to test whether the association between maternal serum 4-HBP and maternal

Table 3 Median and range for birth outcome variables in the newborn girls and boys.

	Median	Min	Max
Female infants (n=72)			
Gestational age (weeks)	39	33	42
Weight (g)	3246	1351	4385
Length (cm) ^a	50	42	57

Abdominal cir. (cm) ^b	32	22	38
Male infants (n=85)			
Gestational age (weeks)	40	32	42
Weight (g) ^c	3494	1560	4916
Length (cm)	51	39	56
Head cir. (cm)	35	28	38
Abdominal cir. (cm) ^b	33	26	38

^aBirth length and birth head circumference in female infants were available only in 71 cases; ^bbirth abdominal circumferences were available only in 83 cases for male infants and in 68 cases for female infants; ^cbirth weight for male infants was available only in 84 cases.

IGF-I was modified by IGFBP3 concentrations, we calculated the mediation coefficients for the association of 4-HBP concentrations in maternal serum on IGFBP3 and IGF-I split by sex of the fetus (Table 4). It was estimated that in the boys, 35% of the association of serum 4-HBP to maternal IGF-I could be mediated via an association with IGFBP3 serum concentrations ($P=0.05$).

Associations between maternal UV filter concentrations in the second trimester and birth outcomes

For male infants of the mothers in the medium 4-HBP exposure group, we observed significantly lower birth weight and smaller head and abdominal circumferences ($P=0.04$; $P=0.04$; $P=0.008$ respectively). These associations remained significant when adjusted for gestational age at birth and prepregnancy BMI (Fig. 2 and Supplementary Table 2). Adjustment for smoking did not change the results (data not shown). The effect estimates indicate that boys of mothers from the medium 4-HBP exposure group at birth were on average 240 g lighter, 8 mm smaller in head circumference, and 1.6 cm smaller in abdominal circumference compared to boys of mothers in the low exposure group when adjusted for prepregnancy BMI and gestational age at birth. When IUGR pregnancies were excluded from the models, negative associations with head and abdominal circumferences in male infants of mothers in the medium exposure group were still significant ($P=0.05$ and $P=0.01$, respectively (data not shown)). When 4-HBP concentrations were included in the model as continuous variable, we did not observe any significant association between maternal serum 4-HBP

concentrations in the second trimester and any of the recorded birth outcomes in male infants (Supplementary Table 2).

For female infants, there was no significant association between maternal serum 4-HBP concentrations in the second trimester and any of the recorded birth outcomes (Supplementary Table 2), when adjusting for gestational age at birth. However, in the model where IUGR pregnancies ($n=20$) were excluded, we observed a significantly positive association between maternal serum concentrations of 4-HBP and birth length and head circumference in female infants both when the 4-HBP serum concentration were used as a continuous ($P=0.03$ and $P=0.02$ respectively) and a categorical (trend $P=0.05$ and trend $P=0.04$ respectively) exposure marker (data not shown).

For mothers carrying a male fetus, we observed significantly negative associations of abdominal circumference at birth with maternal urinary concentrations of BP-1 (P value=0.01) and BP-3 (P value <0.007) (data not shown). However, this association was driven by a single mother, who had very high BP-1 (665 ng/mL) and BP-3 (5893 ng/mL) urinary concentrations compared to the other women and whose son was one of the smallest in the study in spite of being born at term. When this mother-child pair was excluded from the models, the associations between BP-1 and BP-3 and abdominal circumference were no longer statistically significant. Also one of the mothers carrying a female fetus had high urinary concentrations of BP-1 and BP-3 (612 ng/mL and 10,034 ng/mL, respectively). No significant associations between maternal urinary concentrations of BP-1 and BP-3 and birth outcomes in female fetuses were observed, regardless if this high exposed mother-female infant pair was included in the model or not.

Table 4 Mediation coefficient for the estimated effect of 1 ng/mL increase in 4-hydroxybenzophenone (4-HBP) concentrations in maternal serum on insulin-like growth factor I (IGF-I) ($\mu\text{g/L}$) directly or indirectly mediated by insulin-like growth factor binding protein 3 (IGFBP3).

Discussion

In our prospective study of 183 pregnant women, we examined the relationship between 2nd trimester exposure to UV filters of the benzophenone type and maternal thyroid hormones, growth factors and birth variable outcomes. We found statistically significant positive association between 4-HBP concentrations in maternal serum and T_4 , IGF-I and IGFBP3 in mothers carrying male fetuses. Furthermore, we observed consistent *negative* associations in male offspring between maternal serum concentrations of 4-HBP and all birth endpoints, although only statistically significant for

Figure 2 Associations between maternal exposure to 4-HBP (low: <0.48 (ng/mL) (n=51) middle: 0.48–0.788 (ng/mL) (n=52) and high: >0.788 (ng/mL) (n=52)) and birth outcomes in male (n=85) and female infants (n=72). Stratification into exposure tertiles is based on study group 2 (n=155). *P<0.05.

birth weight, head and abdominal circumferences, and only for sons of mothers in the middle exposure range. Thus, the associations between 4-HBP and birth outcomes appeared to be U-shaped rather than linear. A non-monotonic dose–response relationship is a phenomenon that has been demonstrated in experimental studies for endocrine-disrupting effects of several chemicals (35, 36), and we speculate that 4-HBP might act in the same way in humans.

With regard to the UV filters BP-1 and BP-3, we did not observe any associations between maternal urinary concentrations and either maternal thyroid hormones, growth factors or birth outcomes. To our knowledge, BP-3 is the only chemical UV filter for which maternal exposure has previously been examined in humans in relation to

maternal thyroid hormones and birth outcomes. A recent study reported negative association between maternal urinary BP-3 and serum fT_3 concentrations (22). In that study, the concentrations of BP-3 found in maternal urine were about 3- 4-fold higher than those in our study population. Furthermore, they did not analyze their data stratified by sex of the infant. These differences could possibly explain the difference in findings between the two studies.

Results of previous studies regarding associations between maternal urinary BP-3 concentrations and birth outcome are equivocal as associations between maternal urinary BP-3 concentrations were observed to be either positively associated with birth weight in boys and negatively associated with birth weight in girls (5) or not

associated to birth weight at all (4, 24). Maternal urinary BP-3 concentrations in the American study (5), which observed associations with birth weight, were on average 3-fold higher than those observed in our Danish study population and in a French study population (4) and 100-fold higher than those observed in a Chinese study population (24); all of which did not observe a significant associations for BP-3 to birth weight. It is possible that associations between maternal BP-3 concentrations and birth weight are only observed at BP-3 exposure level higher than those measured in our study; a study with a larger range of exposure levels would be required to demonstrate whether this is the case.

Maternal exposure to endocrine-disrupting chemicals can affect the fetus by acting directly on the fetus if the fetus is co-exposed through placental transfer of the chemical. However, endocrine-disrupting effects can also affect the fetus indirectly via changes in maternal hormone concentrations, including thyroid hormones (37) and growth factors (38, 39, 40, 41). We observed associations between maternal serum concentrations of 4-HBP and maternal thyroid status, and interestingly, the observed associations differed depending on the sex of the fetus. For mothers carrying a female fetus, the effect estimates indicate that, in relation to median fT_4 concentrations, the highest exposed mothers might have on average 12% lower fT_4 concentrations compared to the lowest exposed mothers. For mothers carrying a male fetus, the highest exposed mothers might have on average 20% and ~22% higher serum T_3 and T_4 concentrations, respectively, than the lowest exposed mothers. During pregnancy, the fetus is highly dependent on maternal thyroid hormone function, especially during the first 20 weeks of gestation. Thyroid receptors, thyroid receptor gene expression and prereceptor control mechanisms are detected in fetal tissues as early as at gestational week 7 (42, 43), demonstrating the importance of thyroid hormones for fetal development already in early pregnancy, long before the fetus's own thyroid hormone production initiates around gestational week 11 and is fully established around mid-gestation (44). Experimental studies indicate that the active hormone T_3 is not transferred from the mother to the fetus; the fetal source comes from metabolism of maternal T_4 reaching fetal tissue; thus, only fT_4 passes the placental barrier from maternal circulation to meet the fetal requirements (45). Even at term, 30% of the fetal thyroid hormones are of maternal origin (44). Low maternal concentrations of fT_4 during early pregnancy, as we observed in the high 4-HBP exposed women carrying a female fetus, have been shown to affect both verbal and

nonverbal cognitive function of infants later in life (46). Hyperthyroidism during pregnancy has, on the other hand, been shown to be associated with increased risk of low birth weight and being small for gestational age (47, 48), which is in agreement with our observation of 4-HBP exposure in women carrying a male fetus being associated with both increased maternal thyroid hormone concentrations and decreased fetal growth. Thus, it is possible that the association with birth size of male offspring in mothers of the middle exposure group to 4-HBP could be mediated by an increase in their thyroid hormones. However, we have previously shown that 4-HBP also might enter the fetal circulation and hence might also act directly on the fetus (3).

We also observed positive associations between maternal serum concentrations of 4-HBP and of the growth factor IGF-I and its major binding protein IGFBP3. During pregnancy, maternal serum concentrations of IGF-I and IGFBP3 increase to reach a maximum at approximately 37 weeks of gestation (27). This increase is positively associated with an increase in placental-derived growth hormone (pGH), which is detectable in maternal serum from week 8 (49) and gradually takes over the function of maternal pituitary growth hormone, which concurrently decrease during pregnancy (38). In the second trimester, pGH therefore plays an important role in stimulating maternal IGF-I production (38, 50) (and indirectly also IGFBP3 production (27)). Maternal IGF-I on the other hand stimulates placental nutrition transport to the fetus (51, 52, 53, 54). Maternal IGF-I has been shown to be associated with placental weight and is believed to be indirectly responsible for fetal growth (27). It therefore seems contradictory that maternal exposure to 4-HBP is associated with both increased maternal IGF-I concentrations and decreased fetal growth as we observed for the boys.

4-HBP is known to be one of the metabolites of benzophenone (BP), and the measured maternal serum concentrations of 4-HBP may therefore, at least partly, originate from exposure to BP and maternal metabolism of BP into 4-HBP (55). However, 4-HBP is also in itself used in industry as a UV absorber and in the manufacture of other substances (6) but not in sunscreens or other personal care products (9). BP is also not allowed to be used in sunscreens as a UV filter, but is still allowed for use in personal care products as flavoring and perfume fixation. In addition, BP is used in washing agents, painting, fillers, pharmaceuticals, lacquers, furniture, electrical equipment and flavoring in candies, and also as a photo-initiator, surfacing and a wetting agent in inks, which often lead to its presence in

recycled paper (10). Experimental studies elucidating effects of 4-HBP exposure are limited but 4-HBP exposure has been reported to exhibit an estrogenic activity both *in vitro* and *in vivo*, while the parent compound BP only shows a weak or no estrogenic activity (16, 21, 56). In humans, maternal urinary 4-HBP concentrations have been associated with a skewed sex ratio with an excess of male birth (13). BP has been shown *in vitro* to decrease thyroid peroxidase (TPO) activity that plays an important role in thyroid hormone synthesis (20). We do not know if BP is metabolized to 4-HBP in the used *in vitro* model (a follicular thyroid carcinoma cell line) and the observed effect therefore potentially could be mediated (partly) by 4-HBP. With a decrease in TPO activity reduced T_3 and T_4 synthesis would be expected, which is the opposite of our findings where we observe higher T_3 and T_4 concentrations with higher 4-HBP concentrations in mothers carrying male infants. However, in contrast to an *in vitro* model, all the compensatory feedback mechanisms are active in our pregnant women and an effect observed in an *in vitro* system is therefore difficult to translate into potential effects *in vivo*.

Limitations and strengths of the study

A limitation of our study is that maternal exposure was estimated based on single spot urine and serum samples. The benzophenone type UV filters are non-persistent chemicals that are expected to be excreted within a few days (depending on the chemical) and thus a concentration measured at a given time reflects only recent exposure. However, intra-individual urinary concentrations of BP-3 have previously been shown to have a relatively high interclass correlation coefficient (ICC) ranging from 0.46 to 0.81 (57, 58, 59) and was demonstrated to be well correlated with other spot samples taken during a longer period within the same individual (59, 60, 61). Therefore, at least for BP-3 but most likely also for BP-1 and 4-HBP, the concentrations measured in a single spot sample is assumed to represent quite well a person's general exposure level. Furthermore, based on our previous study examining several UV filters in different matrices (3), we were able to focus on the most appropriate matrices for BP-1, BP-3 and 4-HBP exposure in this study.

The gold standard for measurement of free thyroid hormones (fT_3 and fT_4) is a method involving a separation step of bound from free thyroid hormone, classically a dialysis method (62) or recently the LC/MS method; but none of these methods are widely available. In our study, free thyroid hormones were measured by an immunoassay. Immunoassays can both overestimate and underestimate

free thyroid hormone concentrations depending on the platform used for the assay (62). However, there is no reason to suspect that a potential overestimation of free T_3 and free T_4 serum concentrations should be biased in relation to the exposure to UV filters and thereby might not have affected the results.

Sample size is always a challenge in studies like this and is limited both by recruitment and cost of analyses. Our study population was a selected group of women undergoing amniocentesis. However, with regard to their exposure to UV filters, we do not think that they are biased compared to the general population for the following reasons: (1) when adjusting for the age of the mother, no significant difference in exposure levels were observed between the women carrying a fetus with malformations or abnormal karyotype and the women carrying a healthy fetus with maternal age or wish as only indication for the amniocentesis procedure and (2) the concentrations of maternal urinary BP-1 and BP-3 measured in our study population was comparable to the concentrations recently measured in pregnant women from the general population (1).

We analyzed the associations of exposure to three different UV filters against seven different hormones and four different birth outcomes, resulting in a large number of tests which increased the risk of a significant result being a chance finding. We thus cannot exclude that some of our significant associations were chance findings. However, the reported findings, especially those observed in male infants, all point in the same direction and are in mutual biological agreement, making them plausible true findings.

Conclusion

In conclusion, in this prospective study of 183 mother-child pairs, we found associations between maternal serum concentrations of the UV filter 4-HBP (used a UV absorber in industrial products) and decrease in birth weight, birth abdominal- and head circumference in male infants. In addition, we found an association with changes in thyroid hormone concentrations and growth factors, predominantly in mothers carrying male fetuses. Those findings are of concern and call for further studies on possible long-term consequences of exposure to UV filters for fetal development and children's health.
