Over the past 3.5 million years, there have been several intervals when climate conditions were warmer than during the pre-industrial Holocene. Although past intervals of warming were forced differently than future anthropogenic change, such periods can provide insights into potential future climate impacts and ecosystem feedbacks, especially over centennial-to-millennial timescales that are often not covered by climate model simulations. Our observation-based synthesis of the understanding of past intervals with temperatures within the range of projected future warming suggests that there is a low risk of runaway greenhouse gas feedbacks for global warming of no more than 2 °C. However, substantial regional environmental impacts can occur. A global average warming of 1–2 °C with strong polar amplification has, in the past, been accompanied by significant shifts in climate zones and the spatial distribution of land and ocean ecosystems. Sustained warming at this level has also led to substantial reductions of the Greenland and Antarctic ice sheets, with sea-level increases of at least several metres on millennial timescales. Comparison of palaeo observations with climate model results suggests that, due to the lack of certain feedback processes, model-based climate projections may underestimate long-term warming in response to future radiative forcing by as much as a factor of two, and thus may also underestimate centennial-to-millennial-scale sea-level rise.

Depending on the choice of future carbon emission scenarios, projected global surface air temperature changes for the end of this century relative to pre-industrial conditions (defined here as average conditions from AD 1850–1900 (ref. 1)) range from 1.6 °C (0.9 to 2.4 °C, 5–95% confidence interval, Representative Concentration Pathway (RCP) 2.6) to 4.3 °C (3.2 to 5.5 °C, 5–95% confidence interval, RCP8.5 (ref. 1)). Models project substantially higher warming at high latitudes, with Arctic temperature changes being amplified in simulations by a factor of 2 to 3, implying future warming of ~3 °C (RCP2.6) to ~12 °C (RCP8.5) in these regions. Moreover, in most areas, the warming is projected to be greater over land than over the ocean.

Even if future emissions are reduced, warming will continue beyond 2100 for centuries or even millennia because of the long-term feedbacks related to ice loss and the carbon cycle. Given concern about these impacts, the Paris Agreement proposes reducing emissions to limit global average warming to below 2 °C and pursue efforts to limit it to 1.5 °C, effectively defining a climate ‘defence line’.

Although this guardrail concept is useful, it is appropriate to ask whether the global limits proposed in the Paris COP21 climate agreement really constitute a safe operating space for humanity on our complex planet.

Many state-of-the-art climate models may underestimate both the rates and extents of changes observed in palaeo data. Models are calibrated based on recent observations, simplifying some processes (for example, the representation of clouds and aerosols) or neglecting processes that are important on long timescales under significantly warmer boundary conditions (for example, ice-sheet dynamics or carbon-cycle feedbacks). This lack of potentially important feedback mechanisms in climate models underscores the importance of exploring warm climate intervals in Earth’s history. Understanding these past intervals may illuminate feedback mechanisms that set long-term climate and Earth system sensitivity (ESS), enabling an assessment of the possible impacts of warming on physical, biological, chemical and ecosystem services on which humanity depends.

A full list of authors and affiliations appears at the end of the paper.
Examples of such warmer conditions with essentially modern geographies can be found in Fig. 1 during the Holocene thermal maximum (HTM) and the Last Interglacial (LIG; ~129–116 thousand years ago (ka), where present is defined as 1950). Here, the HTM is broadly defined as a period of generally warmer conditions in the time range 11–5 ka, which, however, were not synchronous in their spatio-temporal expression. The LIG can also be compared to the warmer peak interglacial Marine Isotope Stage (MIS) 11.3 (~410–400 ka), where climate reconstructions exist. Note that these times of peak warmth were associated with different orbital parameters, and thus different spatial and seasonal distribution of solar insolation, while their greenhouse concentrations were close to pre-industrial levels and their temperatures, although within the projected range of anthropogenic warming for the near future, have been controlled by a different blend of forcing mechanisms (see section ‘Earth system responses during warm intervals’). Accordingly, past interglacials can be thought of as a series of natural experiments characterized by different combinations of climate boundary conditions. Although they are not strict analogues for future warming, these past warm intervals do illustrate the regional climate and environmental response that may be triggered in the future, and thus remain useful as an observational constraint on projections of future impacts.

The HTM is amenable to detailed reconstruction based on data availability and more refined approaches to chronology, but the older interglacial intervals illustrate greater warming and impacts. To examine past climates with greenhouse gas concentrations of >450 ppm (as expected for RCP2.6), we must look farther back in time, to the mid-Pliocene warm period (MPWP), 3.3–3.0 million years ago (Ma), when atmospheric CO₂ was between 300 and 450 ppm² (Fig. 1) and warm conditions lasted long enough to approach equilibrium. Older intervals, such as the early Eocene climatic optimum (EECO, ~53–51 Ma) offer an opportunity to study extremely high-CO₂ scenarios (900–1,300 ppm) that are comparable with the fossil-fuel-intensive RCP8.5 scenario²⁸ (>1,200 ppm); however, these older intervals had continental configurations significantly different from today.

Palaeo evidence over the last 2,000 years and during the Last Glacial Maximum (LGM) was discussed in detail in the Fifth Assessment Report of the Intergovernmental Panel for Climate Change. Here, we focus on the climate system responses during the three best-documented warm intervals, the HTM, LIG and MPWP (Figs. 1 and 2), and address spatial patterns of environmental changes and the forcing leading to them. Observations on the spatial temperature expression of these warm periods and their forcing are presented in Box 1, which also includes a discussion of the limitations of these time intervals as first-order analogues for future global and regional warming. Palaeo evidence on the Earth system response to these warmer conditions is reviewed in the next section (summarized in Fig. 3). The section ‘Amplification and thresholds: palaeo lessons for the future’ discusses potential feedbacks and thresholds in the climate system in light of the palaeo record and their implications for future warming impacts. Based on the palaeo evidence on climate, sea level and past CO₂ in warm intervals, we assess the long-term ESS¹¹ as imprinted in the palaeo record in Box 2 and draw conclusions on limitations of current climate models to predict the long-term (millennial) change in Earth’s climate. Given its different continental configuration, we limit our analysis of the EECO to the issue of ESS in Box 2, based on available palaeo data and published model experiments where we account for the global effects of changing distribution of landmasses at that time.

**Earth system responses during warm intervals**

Changes in temperature conditions lead to significant regional responses in the Earth system. In the following sections, past changes in important components of the Earth system are summarized, for which the palaeo record allows us to draw conclusions for a future warming of 2 °C and beyond.

---

**Fig. 1 | Changes in global climate and radiative forcing over the last 4 Myr.**

- **a.** Changes in global surface air temperature (GSAT: Snyder²⁹ (blue line) with 2.5% and 97.5% confidence intervals (light blue shading), Hansen et al.¹⁰⁴ (grey line)) reconstructed from proxy records (left y-axis) and changes in atmospheric CO₂ (right y-axis) from ice-core air bubbles (red line: Bereiter et al.¹⁰⁷) and marine CO₂ proxies (light orange dots: Bartoli et al.), dark orange dots: Hönsch et al., green dots: Martinez-Botí et al.) over the last 4 Myr. **b.** Same as in a for the last 800,000 years. **c.** Same as in a and b for the last 160,000 years. **d.** GSAT reconstructed from proxy records by Marcott et al.¹⁰⁷ over the Holocene (blue line with 2.5% and 97.5% uncertainty limits in light blue shading) and the Past Global Changes (PAGES) 2k Consortium¹⁰⁸ (purple line) together with changes in atmospheric CO₂ from ice-core air bubbles (red line). **e.** Measured GSAT over the last 150 years (HADCRUT4 (ref. ¹, black line)) and reconstructed from proxy records over the last 2,000 years¹⁰⁸ (purple line, 30 bins with 2.5% and 97.5% bootstrap confidence limits in grey shading). Note that temperatures in d–e are given as anomalies relative to the pre-industrial mean, where pre-industrial is defined as the time interval 1850–1900. Proxy data in a–c are not available in sufficiently high resolution to unambiguously quantify a mean for this short time interval. Accordingly, panels a–c are given relative to an extended pre-industrial reference time interval of the last 1,000 years. The horizontal yellow bars indicate the 1.5–2 °C warming target relative to pre-industrial of the Paris agreement. T, temperature; PI, pre-industrial.
Box 1 | Global and regional temperature changes in past warm intervals

The HTM surface warming relative to pre-industrial conditions was on average <1 °C (ref. 107) and is mostly expressed in Northern Hemisphere proxies that are sensitive to the warm season. Although some regional studies define the HTM narrowly as older than 8.2 ka, here we take a broad definition of ~11–5 ka. We exclude the 8.2 ka cold event in the North Atlantic region, which is thought to have been caused by a freshwater disturbance in the North Atlantic and subsequent weakening of the AMOC, and is not representative of a global warming response expected for the end of this century.

The HTM was a complex series of events in which warming occurred while ice cover and sea level had not reached postglacial equilibrium and continental ice sheets in North America and Scandinavia were still retreating. This complexity of residual ice cover makes it likely that HTM warming was regional, rather than global, and its peak warmth thus had different timing in different locations. Ice-core data show that radiative forcing due to greenhouse gases during the HTM was slightly lower than pre-industrial values. Compared to pre-industrial conditions, the HTM orbital configuration featured greatly enhanced summer insolation in high northern latitudes and reduced winter insolation below the Arctic Circle. On an annual average, HTM insolation was higher at high latitudes, but slightly lower in the tropics.

Global-average and high-northern-latitude surface temperatures during the HTM appeared to be warmer (at least during summer) than today, while low-latitude climates were slightly cooler, consistent with annual orbital forcing. Although substantial warming was found in the North Atlantic marine sector between 11 and 5 ka (ref. 107), recent reconstructions of climate in the mid-northern latitudes of continental North America and Europe based on pollen data were characterized by a cooler HTM with a slow warming as the continental ice sheets retreated. In contrast, Greenland's mean annual atmospheric temperature (after correction for ice-sheet altitude changes) peaked earlier, between 10 and 6 ka (refs 132,133), and was warmer than pre-industrial by 1–4 °C (ref. 137), while the Nordic seas were only warmer by ~0.5–1 °C (ref. 118). The North Pacific Ocean also displayed an early Holocene warming, and in most areas a mid-Holocene cooling relative to today, but warming in the North Pacific and East Asia occurred earlier than in the Atlantic sector. Peak warming in the Bering Sea (1–2 °C), the western subpolar North Pacific (1–2 °C) and the Sea of Okhotsk (2–3 °C) occurred between 9 and 11 ka, with a possible second warm event between 7 and 5 ka in the Sea of Okhotsk.

In the subpolar Northeast Pacific off Alaska, peak warming (~1 °C above modern, ~3 °C above mid-Holocene) occurred near 11 ka (ref. 139), and in the Pacific off Northern California, peak warmth occurred in two events near 11 ka and again near 10 ka (ref. 120).

In summary, the HTM is a complex regional series of events, best expressed at higher northern latitudes, earliest in the North Pacific marine sector, substantially delayed on land areas influenced by residual ice, and slightly delayed in the North Atlantic and Greenland sector relative to North Pacific and East Asian locations. Although its regional expression makes it difficult to draw a unique global picture, it nevertheless serves as a well-dated and data-rich example of regionally warmer conditions, and is instructive for the impact of warming in these environments. Its complexity also suggests caution in over-interpreting older intervals as being representative of global climate states, because less data are available and chronological constraints are weaker.

The LIG global-average sea surface temperature (SST) was probably 0.5–1 °C warmer than pre-industrial at least seasonally (Supplementary Table 2). Here, we use the value of 0.5 ± 0.3 °C as best estimate of the global SST warming at 125 ka (ref. 107), a time period when also the northern hemisphere reached a stable warm plateau, although global SST peak warmth may have been somewhat earlier. Using a general scaling of global SST to global surface temperature of 1.6, this implies that global surface temperature was probably ~0.8 °C (maximum 1.3 °C) warmer than pre-industrial and followed a strong orbitally induced maximum in Northern Hemisphere summer insolation after a rise in atmospheric CO₂ concentrations from low ice-age values to levels only slightly higher than pre-industrial (latest data compiled by ref. 139). Similar to the HTM, significant spatial and temporal differences in the expression of the warming exist; extratropical regions showed more pronounced warming, while tropical regions showed only little warming or even a slight cooling in line with modelling results. Temperature reconstructions show a pronounced polar amplification signal in the Arctic during the LIG (see Fig. 2), with northern high-latitude oceans warming by ~1–4 °C and surface air temperatures by ~3–11 °C (refs 109,110,112) relative to pre-industrial. As with the HTM, the LIG warming caused by higher northern summer insolation appears to be more representative for regional high-latitude warming than for low-latitude warming in the future.

The MPWP was subject to intermittently elevated CO₂ (potentially up to 450 ppm) compared to the HTM and the LIG. The CO₂ concentration at that time was most similar to the RCP2.6 scenario, and a factor of three-to-four less than concentrations expected by AD 2100 for the RCP8.5 scenario. Climate models simulate an increase in tropical temperatures by 1.0–3.1 °C (for RCP2.6 CO₂ forcing of 405 ppmv (ref. 3)), generally in line with MPWP proxy reconstructions at low latitudes. Strong polar amplification is observed for the MPWP. For example, proxy data from the North Atlantic and northeastern Russian Arctic indicate a rise of surface air temperatures by ~8 °C (ref. 139) during the MPWP and even higher in the early Pliocene. These regional temperature changes are similar to projected warming at AD 2100 for the RCP8.5 scenario, in spite of the much lower CO₂ rise during the MPWP, and suggest that current models may underestimate the warming response in the Arctic to increased CO₂ concentrations.

Continental ice sheets and changes in sea level. Although alpine glaciers, parts of the Greenland Ice Sheet (GIS) and some sectors of Antarctica may have had less ice during the HTM than today, sea level was still ~26 m (9 ka) to ~2 m (5 ka) lower than present, implying the presence (but ongoing melting) of remnants of the glacial maximum continental ice sheets. Greenland ice sheeted its minimum extent between 5 and 3 ka, perhaps as a slow response to HTM warming.

Global sea-level reconstructions of 6–9 m higher than present during the LIG (and at least that for MIS11.3) require a substantial retreat of at least one of the Greenland and Antarctic ice sheets, but probably a significant reduction of both, relative to their current volumes. During the LIG, the marine-terminating ice sheet in southern and central Greenland retreated to terrestrial margins. While latest ice-sheet and climate model simulations allow for a substantial retreat of the West Antarctic Ice Sheet (WAIS) and potentially parts of East Antarctica, direct observational evidence is still lacking. The GIS was also significantly reduced during MIS11.3 peak warming with only a remnant ice cap in the northern part of Greenland. Cosmogenic exposure dating of subglacial materials under Summit, Greenland, suggest loss of part of the GIS during some warm intervals of the Pleistocene.

Ice sheets existed in Greenland and Antarctica during the MPWP, but their configuration is uncertain. A reconstructed sea-level
rise of 6 m or more implies substantially less global ice than present (upper limit poorly constrained) during the MPWP16, and this calls for a significant shrinkage of the GIS and/or AIS. Model results suggest a significantly reduced GIS23, while geological data show evidence of West Antarctic deglaciation24 and potentially also over the Wilkes subglacial basin in East Antarctica25.

Based on limited observational evidence, generally reduced summer sea ice cover in the Arctic Basin has been reconstructed during the MPWP23 and biomarkers at the Iceland Plateau indicate seasonal sea ice cover with occasional ice-free intervals. During this warm interval, the East Greenland Current may have transported sea ice into the Iceland Sea and/or brought cooler and fresher waters favouring local sea ice formation31.

Marine plankton ecosystem changes. Warmer ocean temperatures influenced marine ecosystems. The HTM warming was regionally diachronous and therefore did not leave a globally consistent fingerprint on the surface-layer plankton habitat32. There is nevertheless abundant evidence for changes in productivity, such as in the North Pacific, where early Holocene warming appears to have promoted diatom blooms and enhanced export production in warmer, more-stratified surface waters33.

A reorganization of ocean productivity was also documented during the LIG, with evidence for increased frequency and poleward expansion of cocolithophore blooms34 and higher export production in the Antarctic Zone of the Southern Ocean35,36. Strongly increased export production is also found in the Southern Ocean during the MPWP37. The impacts of these changes on higher
trophic levels and benthic ecosystems remain unexplored, except in the climatically sensitive marginal seas. Here, circulation changes during past warm intervals led to local extinctions and community reorganization in marine ecosystems38, with a stronger response to LIG climate forcing than in the Holocene.

Whereas HTM and LIG marine communities are good compositional and taxonomic analogues to the present, MPWP marine ecosystems differ due to substantial species turnover (extinctions and originations)39. In some groups of plankton, such as in planktonic foraminifera, enough extant species existed in the MPWP to judge general ecosystem shifts40. Data from these groups indicate that poleward displacement of mid- and high-latitude marine plankton during the MPWP was stronger than during the LIG, but the diversity–temperature relationship remained similar and comparable to the present41. Thus, oceanic marine plankton responded to warming with range shifts, rather than by disruption of community structure.

Vegetation and climate on land. Extensive proxy data is available from all continents showing large changes in vegetation and shifts in moisture regimes, indicating that the HTM was complex and temporally variable. For example, major HTM changes in vegetation are marked by greening of the Sahara42, whereas in other regions, including the Northern Great Plains of North America, aridity increased and expanded east into the boreal biome43. Many regions experienced a climate-driven poleward extension of their biome boundaries with similar altitudinal vegetation expansions by a few hundred metres44. The tundra and tundra–forest boundary in eastern North America, Fennoscandia and Central Siberia shifted northward (by ~200 km), while forest shifted southward in eastern Canada (by ~200 km)45. During the LIG, tundra vegetation46 contracted, the Sahara Desert vanished47, and boreal forest vegetation48 and savanna49 expanded. Temperate taxa (hazelnut, oak, elm) were found north of their current distribution in southern Finland45. In Siberia, birch and alder shrubs dominated vegetation compared to herb-dominated tundra at present45. Southwestern Africa was marked by expansion of Nama Karoo and fine-leaved savanna45.

In the MPWP, temperate and boreal vegetation zones shifted poleward (for example in East Asia and Scandinavia)39. Tropical savannas and forests expanded, while deserts contracted45.

Amplification and thresholds: palaeo lessons for the future
Understanding potential amplification effects and non-linear responses in climate and environmental systems is essential, as they have substantial environmental and economic consequences45. Many potential amplification effects are outside of historical human experience, so palaeo data may help understand these processes.

Carbon-cycle feedbacks. Radiative forcing over the last 800,000 years by the atmospheric greenhouse gases CO2, CH4 and N2O was often lower but rarely higher than pre-industrial values46, and greenhouse gas rise rates in past warm periods were much slower. Over the period 1987–2016, global annual greenhouse gas concentrations rose on average by 19 ppm per decade for CO2 (with generally increasing rise rates over this 30 year interval), by 57 ppb per decade for CH4 and by 8 ppb per decade for N2O (all data from https://www.esrl.noaa.gov/gmd/), while during the last deglaciation, high-resolution ice-core data (WAIS Divide and Taylor Glacier, Antarctica) reveal natural rise rates up to a factor of 10 slower (~2 ppm per decade for CO2, ~20 ppb per decade for CH4, and ~1 ppb per decade for N2O (refs 34–36)). While these natural variations in greenhouse gas forcing represent a substantial contribution to glacial–interglacial climate variations, the climate mechanisms that drive changes in the carbon cycle and the associated climate feedbacks remain a matter of debate.

Analyses of last millennium CO2, and northern hemisphere temperature variability suggest a warming-driven net CO2 release from the land biosphere (2–20 ppm per °C) on decadal-to-centennial scales37–39. During short-term warming events in pre-industrial times (when CO2 was rather constant), net release of land carbon due to enhanced respiration of soil and biomass appears to compensate plant growth associated with fertilization effects by higher temperatures. A similar short-term response can be expected for future regional warming.

Peat accumulation rate is positively correlated with summer temperature45, but is a relatively slow process. Peat reservoirs have gradually increased over the Holocene, resulting in long-term sequestration of carbon46. HTM rates for net carbon uptake by northern peatlands were clearly higher than those for the cooler late Holocene46,26 as a result of rapid peatland inception and peat growth during times of ice-sheet retreat and strong seasonality.

While peatlands were present during the LIG47, the preserved record is fragmentary so the magnitude of LIG peat carbon storages is not well constrained. During the Pliocene (and MIS11.3), peats were probably abundant but there are only a few dated peat deposits of this age (for instance, German and Polish lignite48). Boreal-type forested peatlands with thick peat accumulations may have accumulated over >50,000 years in response to warmer climates during the Pliocene47.

Based on these palaeo-environmental analogues, peatlands will probably expand in a 2 °C warmer world on centennial-to-millennial timescales, although the size of this sink is difficult to estimate based on the palaeo record alone and the net carbon source or sink may depend on the rate of warming and moisture conditions. If warming is fast (decadal-to-centennial), carbon may be released via respiration faster than it can accumulate via peat growth. If warming is slower (centennial-to-millennial) continued peat growth may outstrip respiratory losses, yielding a net carbon sink.

Widespread permafrost thaw and enhanced fire frequency and/or severity could counteract carbon sink effects of long-term peat growth49. Today, about 1,330–1,580 gigatons of carbon (GtC) are stored in perennial frozen ground, of which ~1,000 GtC (more than the modern atmospheric carbon inventory) are located in the upper 0–3 m of soil. This frozen carbon is susceptible to a thawing of the upper permafrost layer under future warming45 and risks of the related carbon release can be assessed in ice-core gas records. Although detailed data are limited, the observed variation of CO2 and CH4 in ice-core records suggests that the risk of a sustained release of permafrost carbon is small if warming can be limited to the modest high-latitude warming encountered during past interglacial periods50. Apart from short-lived positive excursions observed at the onset of many interglacials, atmospheric CH4 and CO2 concentrations in the ice record50–52 were not significantly elevated in past interglacials in which the Arctic was significantly warmer than during pre-industrial times50. Accordingly, the additional CO2 and CH4 releases at the onset of interglacials (if they were related to permafrost warming50), were not sufficient or long enough to drive a long-term ‘runaway’ greenhouse warming that outpaces negative feedback effects. If future warming is much greater than that observed for past interglacials, release of carbon from permafrost remains a serious concern that cannot be assessed based on the palaeo evidence presented here.

A release of CH4 from marine hydrates during climate warming, as suggested from marine sediment records53, cannot be confirmed. Isotopic analysis of CH4 preserved in ice cores suggests that gas hydrates did not contribute substantially to variations in atmospheric CH4 during rapid warming events in the glacial and deglacial54–56. This may suggest that long-term CH4 releases are also unlikely to occur in future warming, as long as the magnitudes and rates of warming are limited to the range observed in the geologic record of past warm intervals.
Based on the evidence summarized above, the risk of future massive terrestrial CH₄ or CO₂ releases that may lead to a runaway greenhouse gas effect under modest warming scenarios of RCP2.6 appears to be limited. However, the amount of carbon released from permafrost as CO₂ may amount to up to 100 GtC (ref. 78) and has to be accounted for when implementing policies for future allowable anthropogenic carbon emissions. We cannot rule out net release of land carbon if future warming is significantly faster or more extensive than observed during past interglacials. Furthermore, past increases in CO₂ were mostly driven by changes in the physical and biological pumps in the ocean and—on long timescales—through interactions between ocean and sediments and the weathering cycle. The reconstruction of ocean carbon reservoirs during past warm episodes remains a challenge, and the risk of significant reductions of ocean CO₂ uptake or disturbances in the Atlantic meridional overturning circulation (AMOC) in the future with feedbacks on the carbon cycle are not well constrained.

Thresholds for ice-sheet melting. Models of the GIS suggest extensive and effectively irreversible deglaciation above a certain temperature threshold, but the threshold is model dependent16,77. Marine records of southern GIS sediment discharge and extent suggest that the GIS was substantially smaller than present during three out of the last five interglacials24 with near-complete deglaciation of southern Greenland occurring during MIS11.3 (refs 76,79). This suggests that the threshold for southern GIS deglaciation has already been passed for the polar temperature amplification signal associated with a persistent global warming by 2 °C, that is, within the range of the Paris Agreement (see Fig. 2). Concentrations of cosmogenic radionuclides in bedrock at the base of Summit Greenland have been interpreted to suggest multiple periods of exposure of the western GIS during the last million years31. In contrast, the age of the basal ice at Summit Greenland suggests a persistent northern Greenland ice dome at least for the last million years31. Vice versa, the southern Greenland ice dome existed during the LIG but melted at some time before 400 ka (ref. 79). Marine records suggest the persistence of ice in eastern Greenland for at least the last 3 million years80, which would imply different temperature thresholds for deglaciation of different parts of the GIS.

The WAIS was appreciated by AR5 (ref. 2) and previous assessments as possessing an unstable marine-based geometry, but the thresholds at which strong positive feedbacks would be triggered were unknown, and models failed to reproduce past sea-level contributions7. Several lines of observational evidence suggest episodes of major retreat of marine WAIS sectors12,25. Marine-based sectors of the East Antarctic Ice Sheet (EAIS) are now known to be at similar risk of collapse as those of the WAIS13,84. The main indicator for a substantial AIS contribution to global sea-level rise in past interglacials remains the sea-level proxy record16. The survival of parts of the GIS in the LIG requires a significant retreat of at least part of the AIS. Pliocene reconstructions of sea-level highstands require a substantial contribution of both the WAIS and EAIS but are subject to major uncertainties16.

Since AR5, model simulations are now more consistent with prior theory and sea-level constraints15,19,41. Ice-sheet model simulations suggest that marine ice-sheet collapse can be triggered in sectors of the EAIS and WAIS for a local sub-surface ocean warming of +1–4 °C (refs 38,19,41). However, thresholds for Antarctic marine ice-sheet collapse vary considerably between models and their parameterizations of ice-shelf mass balance and ice dynamics15,19,41,44. While some models predict that Antarctica is now more sensitive than the literature assessed in AR5 (ref. 2), the current geological record85,86 and modelling evidence are not sufficient to rule out or confirm tipping points for individual Antarctic sectors within the 1.5–2 °C global warming range.

Of special societal relevance is also the rate of sea-level increase. Sea-level rise has accelerated over the last century from 1.2 ± 0.2 mm yr⁻¹ between 1901 and 1990 (largely due to thermosteric effects) to 3.0 ± 0.7 mm yr⁻¹ over the last two decades as net melting of glaciers and ice sheets has increased42. Records of palaeo sea-level rise rates expand our view into times when the melting response of the GIS and AIS may have been much larger than today. Sea-level changes
Fundamental to projecting future warming and impacts is the climate sensitivity to radiative greenhouse forcing, that is, the global-average surface air temperature equilibrium response to a doubling of CO$_2$. The multi-model mean equilibrium climate sensitivity of the Coupled Model Intercomparison Project Phase 5 (CMIP5) is 3.2 ± 1.3 °C (ref. 2). These models include most of the ‘fast’ feedback processes that result in the ‘Charney Sensitivity’ (CS), but lack some other important processes. In particular, many models do not include some of the real-world ’slow’ feedback processes relevant for the Earth’s total warming response, such as long-term changes in ice sheets, sea level, vegetation or biogeochemical feedbacks that may amplify or reduce the amount of non-CO$_2$ greenhouse gases in the atmosphere. Furthermore, many models do not include some of the real-world ’slow’ feedback processes relevant for the Earth’s total warming response, such as long-term changes in ice sheets, sea level, vegetation or biogeochemical feedbacks that may amplify or reduce the amount of non-CO$_2$ greenhouse gases in the atmosphere. Furthermore, our understanding of some atmospheric processes under warmer boundary conditions, such as those associated with cloud physics and aerosols, is still limited. The climate models therefore cannot be expected to include realistic long-term feedbacks, which leads to increased uncertainty in climate sensitivity. The long-term climate sensitivity including all these processes is called the Earth system sensitivity (ESS).

Direct correlation of Pleistocene CO$_2$ and temperature reconstructions suggest ESS values of 3–5.6 °C (refs 10,11). These estimates are based on climate change during glacial cycles. They are therefore indicative of sensitivities associated with large varying glacial ice sheets, and may, therefore, not be appropriate for future warming$^{12,13}$. When corrected for land-ice–albedo feedbacks, vegetation and aerosols, climate sensitivities implied by these geological estimates may have been 30–40% lower$^{134}$.

We revisit this issue, comparing our palaeoclimate data synthesis from episodes warmer than today, with published long transient model simulations 10,000 years into the future$^7$ based on a range of CO$_2$ emission scenarios with two fully coupled climate–carbon-cycle Earth system models of intermediate complexity (UVic and Bern3D-LPX). Both models include fully coupled ocean, atmosphere, sea ice, dynamic vegetation and ocean-sediment models with offline ice-sheet models$^2$. Furthermore, we include a published series of equilibrium climate simulations with four dynamic atmosphere–ocean general circulation models, with primitive equation atmospheres (HadCM3L, CCSM3, ECHAM5/MPI-OM, GISS ModelE-R) and one model of intermediate complexity (UVic) under early Eocene boundary conditions$^{10,135}$.

In the figure below, we compare global surface air temperature anomalies (relative to pre-industrial) to CO$_2$ (panel a), ESL rise relative to CO$_2$ (panel b), and sea-level rise relative to surface air temperature anomalies (panel c). Palaeo data represent the three episodes (HTM, LIG, MPWP) discussed earlier; however, HTM sea-level data are excluded as sea level is still strongly increasing by deglacial ice-sheet melt at that time. To expand the range of climate boundary conditions, we also include data from the EECO (~53–51 Ma), when CO$_2$ was around 1,400 ppm and within a likely range of ~900 to 1,900 ppm (ref. 136). EECO conditions include changes in the configuration of the continents, land surface topography

**Temperature and sea-level response to CO$_2$ forcing.**

- **a.** Annual and global mean surface air temperature anomalies (relative to pre-industrial) as a function of atmospheric CO$_2$ concentrations (see Supplementary Tables 1 and 2).
- **b.** ESL rise relative to CO$_2$ levels (see Supplementary Tables 8 and 10).
- **c.** ESL rise relative to surface air temperature anomalies.
- **d.** Peak rates of ESL rise as a function of coeval surface air temperature anomalies. Black diamonds show simulations of future scenarios by two models of intermediate complexity$^7$, blue triangles are model ensemble mean equilibrium simulations under EECO boundary conditions$^{10,135}$, green squares show EECO simulation responses due to changes in CO$_2$ concentrations alone, estimated by removing the effects associated with the planetary surface boundary conditions relative to pre-industrial control, and red squares are palaeo-reconstructions (Supplementary Tables 8–11). Atmospheric CO$_2$, surface air temperatures and ESL-level values are averaged over AD 10000–12000 in future simulations (black diamonds, a–c). Peak rates of simulated sea-level rise occur earlier, between the twenty-third and twenty-sixth centuries AD, and are compared to coeval transient model temperatures. The red arrows in b and c indicate minimum uncertainties. For ESLs (b–d), EECO values include melting of the full modern inventory of ice, plus steric effects (see Supplementary Table 10 for details). Changes in ocean basin shape are excluded from the EECO ESL calculation.
and albedo changes for loss of continental ice sheets. To separate fast and slow feedbacks, we show EECO model ensemble surface air temperature anomalies, including all boundary conditions (blue triangles) and values extracting the component related to modified land surface albedo due to the removal of ice sheets (green squares), in panel a of the figure. Model simulations suggest that the loss of ice at the EECO accounts for 0.2 to 1.2 °C (ref. 127).

Transient model projections of future warming in response to CO₂ (panel a, black diamonds; see Supplementary Tables) indicate model ESS of ~3 °C, a factor of two lower than inferred from the palaeo data for the EECO (red squares, see also Supplementary Tables 1 and 2). EECO model ensemble estimates of warming (after removing the effect of changing surface albedo, green squares) are essentially identical to the transient future runs. The EECO simulations that include the effect of surface albedo (blue triangles) are closer to the palaeo reconstructions, but still underestimate the inferred EECO warming at high CO₂, so including interactive land ice as a feedback is essential to reproduce the ESS derived from palaeo evidence. This finding echoes previous concern that models built to reproduce present-day climate conditions may be insufficiently sensitive to long-term change 1.

For modest CO₂ rises associated with the MPWP, modelled sea-level changes are generally consistent with palaeo data, but for larger CO₂ rises the models underestimate the largest sea-level rise, such as those reconstructed with larger uncertainties for the EECO (panel b). The UVic model appears to have reasonable sensitivity for the relationship between sea-level rise and warming (panel c; note uncertainty of the ESL rise for MPWP). The underestimation of observed past sea-level rises by the models is therefore probably due to an underestimation of warming. This misfit becomes important because the rate of sea-level rise in the models is dependent on the extent of warming (panel d). If the models were more sensitive to radiative forcing in particular on long timescales (by up to a factor of two, if they are supposed to fit the palaeoclimate data), this would imply an increase by a factor of two to three in the rate of sea-level rise.

While simulations of climates similar to present-day conditions, such as the HTM, agree reasonably well with palaeo records, the differences become more substantial for climates that were significantly warmer (MPWP, EECO), but which are also subject to larger uncertainties in temperature and CO₂ reconstructions. Climate models underestimate polar amplification (see section ‘Continental ice sheets and changes in sea level!’ in the Arctic, as well as global mean temperatures, and therefore also underestimate the extent and rate of sea-level rise. Hence, climate models are still missing or misrepresenting key processes needed to simulate the dynamics of warmer climates on long timescales. Potential caveats include misrepresentations of cloud physics and aerosols 128,129, ocean and atmosphere circulation changes, and insufficient representations of ice-sheet and carbon-cycle feedbacks.

Although state-of-the-art climate models plausibly have correct sensitivity for small magnitude and near-term projections (such as RCP2.6 at year 2100), they can be questioned to provide reliable projections for large magnitude changes (such as RCP8.5) or long-term climate change (beyond 2100), when Earth system feedbacks become important, and for which the models probably underestimate sensitivity.

within the LIG were likely between 3 and 7 mm yr⁻¹ (1,000-year average), with a 5% probability of >11 mm yr⁻¹ (ref. 89). For example, exposed fossil coral reefs from Western Australia 87 suggest that, after a period of eustatic sea level (ESL) stability (127 to 120 ka), sea level rose quite quickly from 2.5 to nearly 8.5 metres in less than 1 ky (that is, 6 mm yr⁻¹). Indirect evidence for sea-level rise from Red Sea isotopic measurements within the LIG allows rise rates as high as 16 mm yr⁻¹ (ref. 90). All of these estimates are uncertain for both the past and are subject to regional isostatic effects but multimetre-scale sea-level oscillations within the last interglacial cannot be excluded 87. They highlight the possibility that future sea-level rise may be significantly faster than historical experience as also suggested in recent satellite altimeter data 91.

Response of land ecosystems. The palaeo record suggests sensitivity of forest ecosystems, specifically in ecotone positions, to moderate warming (1–2 °C) at the decadal-to-centennial scale 82,23, with tipping points reached in regions where moisture availability will go below critical ecophysiology levels for trees 34. At higher latitudes and in mountain ranges, increased temperatures will promote forest expansion into tundra 82. Such northward shifts of boreal ecosystems will be counterbalanced by forest die-back in areas where increased drought will instead favour open woodlands or steppe 82.

Evidence from the HTM suggests that cool-temperate and warm-temperate (or subtropical) forests may collapse in response to climate warming of 1–2 °C, if moisture thresholds are reached 88, and flammable, drought-adapted vegetation will rapidly replace significant impacts on the Earth system are to be expected. Terrestrial and aquatic ecosystems will spatially reorganize to adapt to warmer conditions as they did in the past (for example, during the HTM or LIG). However, human interferences other than climate change, such as pollution, land-use, hunting/fishing and overconsumption, appear to have a much larger influence on species extinction and diversity loss 102 than climate warming.

Conclusions

Past warmer worlds were caused by different forcings, which limits the applicability of our findings to future climate change. Nevertheless, we can conclude that even for a 2 °C (and potentially 1.5 °C) global warming—as targeted in the Paris Agreement 101—significant impacts on the Earth system are to be expected. Terrestrial and aquatic ecosystems will spatially reorganize to adapt to warmer conditions as they did in the past (for example, during the HTM or LIG). However, human interferences other than climate change, such as pollution, land-use, hunting/fishing and overconsumption, appear to have a much larger influence on species extinction and diversity loss than climate warming.

The risk of amplification, such as runaway greenhouse gas feedbacks, appears—based on the palaeo record—to be small under the modest warming of RCP2.6. From this perspective, staying in a range of warming experienced during the past interglacial periods is appropriate to limit risks and impacts of climate change 87. Although these findings support the 2 °C global warming target of the Paris Agreement, more rapid or extensive warming in scenarios such as RCP8.5 would be outside the experience provided by past interglacial periods reviewed here. Such a pathway into conditions without well-studied precedent would be inherently risky for human society and sustainable development.

However, even a warming of 1.5–2 °C is sufficient to trigger substantial long-term melting of ice in Greenland and Antarctica

**Box 2 | Constraining climate sensitivity from past warm periods (Continued)**
and cause sea-level rise that may last for millennia. For instance, the LIG and MIS11.3 were characterized by prolonged warmer-than-present-day conditions in high latitudes, leading to melting of parts of Greenland and Antarctica. This ice-sheet melt contributed to a more than 6 m sea-level rise compared to pre-industrial, on timescales of millennia, and caused significantly higher rates of sea-level rise compared to those of the last decades.

Comparison of palaeo data and model estimates of long-term (multi-centennial-to-millennial) warming in response to CO₂ (see Box 2) suggests that models may underestimate observed polar amplification and global mean temperatures of past warm climate states by up to a factor of two on millennial timescales. Despite the significant uncertainties in climate and CO₂ reconstructions for many of the past warm intervals, this underestimation is probably because the models lack or potentially simplify key processes such as interactive ice sheets, cloud processes and biogeochemical feedbacks that impact long-term ESS. Again, this implies that long-term sea-level rise and regional and global warming may in the long run be significantly more severe than state-of-the-art climate models project.

Knowledge gaps remain for all periods and all processes, including the reconstructions of past CO₂ concentration, air and ocean temperatures and ecosystem responses, but also for extreme events, and changes in variability (see Supplementary Information). It will be important to increase our understanding of cloud and aerosol physics, to improve the representation of cryosphere climate and biogeochemical Earth System feedbacks in climate models used for long-term projections, and to refine palaeo reconstructions as a key constraint for modelled climate sensitivity. In spite of existing uncertainties, our review of observed palaeo data and models associated with known warmer climates of the past underscores the importance of limiting the rate and extent of warming to that of past interglacial warm intervals to reduce impacts such as food and ecosystem disruptions, loss of ice, and the inundation of vast coastal areas where much of the world’s population and infrastructure resides.

Data availability. All data and model results used in this Review Article are from published literature (see references provided in the main text and the Supplementary Tables).
