Abstract

Mating-type switching in \textit{Schizosaccharomyces pombe} entails programmed gene conversion events regulated by DNA replication, heterochromatin, and the HP1-like chromodomain protein Swi6. The whole mechanism remains to be fully understood. Using a gene deletion library, we screened ~3400 mutants for defects in the donor selection step where a heterochromatic locus, \textit{mat2-P} or \textit{mat3-M}, is chosen to convert the expressed \textit{mat1} locus. By measuring the biases in \textit{mat1} content that result from faulty directionality, we identified in total 20 factors required for donor selection. Unexpectedly, these included the histone H3 lysine 4 (H3K4) methyltransferase complex subunits Set1, Swd1, Swd2, Swd3, Spf1 and Ash2, the BRE1-like ubiquitin ligase Brl2 and the Elongator complex subunit Elp6. The mutant defects were investigated in strains with reversed donor loci (\textit{mat2-M mat3-P}) or when the \textit{SRE2} and \textit{SRE3} recombination enhancers, adjacent to the donors, were deleted or transposed. Mutants in Set1C, Brl2 or Elp6 altered balanced donor usage away from \textit{mat2} and the \textit{SRE2} enhancer, towards \textit{mat3} and the \textit{SRE3} enhancer. The defects in these mutants were qualitatively similar to heterochromatin mutants lacking Swi6, the NAD\textsuperscript{+}-dependent histone deacetylase Sir2, or the Cln4, Rfa1 or Rik1 subunits of the histone H3 lysine 9 (H3K9) methyltransferase complex, albeit not as extreme. Other mutants showed clonal biases in switching. This was the case for mutants in the NAD\textsuperscript{+}-independent deacetylase complex subunits Cnr1, Cnr2 and Cnr3, the casein kinase CK2 subunit Ckb1, the ubiquitin ligase component Pof3, and the CENP-B homologue Cbp1, as well as for double mutants lacking Swi6 and Brl2, Pof3, or Cbp1. Thus, we propose that Set1C cooperates with Swi6 and heterochromatin to direct donor choice to \textit{mat2-P} in M cells, perhaps by inhibiting the \textit{SRE3} recombination enhancer, and that in the absence of Swi6 other factors are still capable of imposing biases to donor choice.
Effects of chromatin structure on recombination can be studied in the fission yeast *S. pombe* where two heterochromatic loci, *mat2* and *mat3*, are chosen in a cell-type specific manner to convert the expressed *mat1* locus and switch the yeast mating-type. The system has previously revealed the determining role of heterochromatin, histone H3K9 methylation and HP1 family protein Swi6, in donor selection. Here, we find that other chromatin modifiers and protein complexes, including components of the histone H3K4 methyltransferase complex Set1C, the histone H2B ubiquitin ligase HULC and Elongator, also participate in donor selection. Our findings open up new research paths to study mating-type switching in fission yeast and the roles of these complexes in recombination.

**Introduction**

The fission yeast *S. pombe* exists as two haploid cell types, plus (P) and minus (M), that differ at the *mat1* locus. When starved for nitrogen, haploid cells undergo sexual differentiation, mate with the opposite cell type and sporulate. These events are driven by master regulators expressed from the *mat1-P* and *mat1-M* alleles [1]. The regulators first drive sexual differentiation and mating and, when co-expressed in the zygote, meiosis and sporulation. Homothallic (*h*90) colonies sporulate very efficiently because they contain equal proportions of P and M cells due to frequent gene conversions at *mat1*. The genetic information at *mat1* is replaced with genetic information copied from one of two silent loci, *mat2-P* or *mat3-M* [2]. The organization of the ~35 kb region of chromosome 2 that comprises *mat1*, *mat2-P* and *mat3-M* in *h*90 strains is depicted in Fig 1A. All three loci are flanked by short regions of sequence identity, the centromere-distal H1 box and the centromere-proximal H2 box. In addition, H3 homology boxes immediately adjacent to H2 are found exclusively at *mat2-P* and *mat3-M*. An alternative arrangement, known as *h*09, has *mat2-M* and *mat3-P* cassettes [3].

Mating-type switching follows the so-called 'Miyata's rules' inferred from pedigree analyses of dividing cells [4]. A single *h*90 cell produces both ‘unswitchable’ and ‘switchable’ cells. According to the ‘one-in-four-rule’, illustrated in Fig 1B, one of two sister cells originating from an ‘unswitchable’ cell becomes ‘switchable’. That cell produces one switched daughter upon cell division and one unswitched, but switchable, daughter. Thus, only one cell out of four cousins displays a switched mating-type (the ‘one-in-four’ rule [4]) and lineages of ‘switchable’ cells are observed (the ‘recurrent switching’ rule [5]). The known mechanisms of mating-type switching provide an explanation for these rules.

Mating-type switching is initiated by an imprint at *mat1* introduced during DNA replication [6, 7]. Replication stalls within *mat1* at the *MPS1* site and a nick or two ribonucleotides are incorporated into the lagging strand at the imprinting site situated nearby, at the junction of the *mat1* cell-type specific information and *H1* box [6–15]. This imprint creates a ‘switchable’ cell. During the next round of DNA synthesis, the imprint is converted into a double-strand break (DSB) that triggers homologous recombination and mating-type switching [10, 14]. At least seven factors (Swi1, Swi3, Pol1 (Swi7), Sap1, Lsd1, Lsd2 and Mrc1) are required for efficient DSB formation. The Swi1-Swi3 complex and Mrc1 are necessary for imprinting by pausing replication forks at *MPS1* [7, 16]. The DNA primase Pol1 and a DNA element targeted by the essential DNA-binding protein Sap1 are not required for replication fork stalling at *MPS1*; hence Pol1 and Sap1 are believed to catalyze imprint formation downstream of the Swi1-Swi3 complex [7], while Lsd1 and Lsd2 are required upstream of Swi1-Swi3 [17, 18]. In addition, Swi1, Swi3 and Mrc1 block replication from the *mat1* distal side at the replication
termination site RTS1 to optimize mating-type switching [7, 16]. Thus, replication proceeds unidirectionally when leading-strand synthesis reaches the imprint and the nick is converted into a one-ended DSB.

The DSB end initiates repair by recombining with one of the heterochromatic and transcriptionally silent cassettes mat2-P and mat3-M [10, 19, 20]. The free DNA end can invade either mat2-P or mat3-M, however mating-type information opposite to the information present at mat1 is chosen with a ~90% probability, leading to Miyata’s observation that switchable cells nearly always switch to the opposite mating-type [4, 9]. Surprisingly, this strongly biased
donor selection relies on the heterochromatic state of the mat2-mat3 region [3, 21–24]. In the wild-type, histone H3K9 methylation deposited between the inverted repeat boundaries IR-L and IR-R permits the binding of the key switching factor Swi6, an HP1 homolog [25]. Defective donor choice in swi6 mutants biases h90 cell populations towards the M mating-type due to preferred use of a mat3-M adjacent recombination enhancer over a mat2-P adjacent enhancer in the absence of Swi6 [22, 23, 26]. Also essential at this step of switching is the Swi2-Swi5 complex, capable of interacting with Swi6, and whose molecular role is inferred from the related Sfr1-Swi5 complex [27, 28]. Sfr1 shares sequence homology with the C-terminus of Swi2, in a domain that permits the interaction of either Swi2 or Sfr1 with the recombination mediator Swi5 and with the strand-exchange factor Rad51. The Sfr1-Swi5 complex stabilizes Rad51 filaments in vivo and promotes Rad51-mediated strand exchange in vitro [28–30]. Consistent with similar functions for the Swi2-Swi5 complex, Swi2-Swi5 interacts with Rad51 in two-hybrid assays [27]. Thus, mechanistically, the ability of Swi2-Swi5 to interact with Swi6 suggests that the complex participates in donor choice by biasing strand invasion [27]. This idea is supported by cell-type specific associations of Swi2 and Swi5 with the mating-type region [22]. Swi2 localizes to the mat2-P and mat3-M adjacent enhancers SRE2 and SRE3 (Swi2-dependent recombination enhancer element 2 and 3) in M cells, but only to SRE3 in P cells [22, 23]. In swi6 mutant cells, Swi2 localizes only to SRE3, as in P cells [22]. These observations indicate that the heterochromatin-mediated localization of Swi6 regulates Swi2-Swi5 localization to SRE2 to choose mat2-P [22, 23, 31].

After strand invasion into the homologous sequence at the H1 homology box, the donor locus information is copied by polymerase extension until it reaches the H3 homology box, then H3 is believed to form a hairpin loop structure [32]. The mismatch repair Msh2 (Swi8)-Msh3 (Swi4) complex recognizes this conformation and DNA synthesis stops at the donor cassette. The Rad51 mediator Rad55-Rad57 has been suggested to work together with Msh2 (Swi8), because mutants in these factors tend to form h\textsuperscript{+N} rearrangements containing a duplication of the entire mat2-3 region at mat1 [33–36]. In addition to Rad55-Rad57, the homologous recombination factor Rad52 is required for DSB repair at mat1 [37, 38]. Presumably, Rad55-Rad57 and Rad52 are involved in annealing between two H2 boxes in mat1 and the donor cassette. The endonuclease Rad16 (Swi9)-Swi10 and its activator Pxd1 cleave the intermediate between the H2 and H3 boxes [37, 39]. This is followed by new DNA synthesis from H2 of mat1 to H1 to complete replication of this region and to thus switch mating-type.

This switching system has been utilized to study multiple aspects of replication, histone modification and recombination. Historically, the mating-type switching related genes were classified functionally by Southern blotting analysis of the effect of mutants on mat1 switching [40]. Class Ia genes (swi1, 3, and 7) are required for the imprinting step that leads to the DSB formation, hence mutants in these genes show no DSB in a Southern blot. Class Ib genes (swi2, 5 and 6) are not necessary for DSB formation, but required for efficient switching. The third group, Class II, (swi4, 8, 9, and 10) resolves the recombination intermediate, mutants in these genes contain frequent rearrangements of the mating-type region, in particular the h\textsuperscript{+N} duplication. Subsequent screens identified additional factors (Table 1) and suggested that yet more might exist. In particular, aspects of imprint formation and donor choice are still not understood.

To identify yet unknown regulators of mating-type switching, we combined the deletion of 3420 nonessential genes (Bioneer gene deletion library version 5) with an h90 strain background. The strain also included a dual reporter system with CFP under the control of a P-specific promoter and YFP under the control of an M-specific promoter, so that the ratio of P-to-M cells was determined by comparing CFP and YFP fluorescence. As a secondary screening strategy, the genetic content at mat1 was quantified with multiplex PCR using genomic DNA
### Table 1. Mating-type switching related genes.

https://doi.org/10.1371/journal.pgen.1007424.t001
isolated from the candidates that passed the initial screen. These extensive screens identified several new mating-type switching genes whose deletion results in a bias toward M cells within $h^{90}$ populations instead of the balanced P:M ratio. In addition, analysis of $h^{90}$ strains revealed that some strains showed clonal biases in independent colonies. As mentioned above, Swi6 is an essential directionality factor [3, 22, 23]. Epistasis analysis with swi6Δ suggests that Clr4, Sir2, Swd1, Clr3 work in the same pathway as Swi6, whereas Brl2, Pof3 and Cbp1 act via Swi6-dependent and -independent mechanisms. These observations provide new clues to understand the molecular mechanisms of mating-type switching.

Results and discussion
Identification of mating-type switching defective mutants

We conducted a genome-wide screen for factors required for mating-type switching. The screen used an S. pombe gene deletion library (Bioneer) consisting of 3420 haploid strains, each of which lacks a non-essential gene. Mating-type switching occurs in $h^{90}$ strains, yet the Bioneer library strains are heterothallic $h^{+N}$ strains for which a large duplication in the mating-type region abrogates mating-type switching. To construct $h^{90}$ derivatives of the entire Bioneer collection, strain PG4045 was mated to the library. The $h^{90}$ mating-type region of PG4045 could be selected in the progeny due to the linked LEU2 gene. In addition, PG4045 contains two fluorescent reporters specific for the P (CFP controlled by the map2 promoter) and M (YFP controlled by the mfm3 promoter) cell types, respectively. Both reporters are expressed from the leu1 locus where they were integrated together with the selectable ura4+ gene. Thus, we selected $h^{90}$ LEU2 ura4+ segregants (S1 Fig). We obtained 3298 $h^{90}$ deletion strains in which we monitored expression of the fluorescent reporters (Fig 2A). Efficient mating-type switching results in rapid homogenization of $h^{90}$ cell populations to equal proportions of P and M cells (Fig 1B). Here, screening specifically for mutants that displayed biased cell-type ratios, differing by >3 standard deviations from the mean, we isolated 105 candidates with skewed proportions (Fig 2B, S2 Fig, S2 Table). In several deletion strains, we detected co-expression of CFP and YFP in a cell. This phenotype was most likely caused by derepression of the mating-type information at mat2-P and mat3-M in these mutants [42]. In addition, 568 strains that could not be evaluated due to low fluorescence intensity or poor growth were examined by iodine staining, a stain for S. pombe spores that can be used as diagnostic for mat1 switching (Fig 2C, S3 Table). Wild-type $h^{90}$ colonies are stained darkly by iodine vapors because of their high spore content while mutants with altered mating or sporulation are stained less. Here, 124 deletion strains among the strains tested showed a staining different from wild-type. They were analyzed by quantitative multiplex PCR for mat1 content alongside the 108 candidates that had passed the fluorescence microscopy screening. Analyzing the content of mat1 permitted us to pinpoint mutants for which biased cell-type expression or poor sporulation is likely to result from switching defects. A number of candidates failed to show a biased mat1 content by multiplex PCR according to the chosen thresholds of P band intensity (Fig 2A and 2D). Indeed, many mutations might result in biased reporter gene expression or altered sporulation without affecting mating-type switching, for example genes located in the I region of the mat locus were eliminated from this screening. In addition, 35 deletion mutants that were diploid and/or heterothallic ($h^{+N}$) were eliminated from the list of candidates (S4 Table). A bias in mat1 content was detected for 32 mutants, in all cases towards mat1-M, suggesting an increased use of mat3-M. The identity of the deleted gene in these mutants was confirmed using published barcode sequences or gene specific primers. Surprisingly, 9 genes encoding ribosomal proteins are in the list, possibly as a consequence of protein synthesis defects. We did not pursue the investigation of these mutants, but
focused instead on the remaining 23 mutants. These included nearly all known non-essential switch-related genes, 16 of which were identified in total. A few switch-related genes (swi1, 5 or 10) were not deleted in the Bioneer library and were therefore not tested by the screen. A few other mutants might have escaped detection due to clonal variation, alternative switching phenotype with low frequency as for msc1Δ [49] or due to a switching bias close to the set thresholds, as for mrc1Δ [16]. Globally though the screening strategy was strongly validated by
the identification of known switch-related factors alongside novel factors. The 7 newly identified factors include the F box protein Pof3, the CK2 family regulatory subunit Ckb1, the elongator complex subunit Elp6, the E3 ubiquitin protein ligase Brl2 and three subunits of the Set1/compass complex (Set1C), Swd1, Swd2 and Spf1 (Fig 2D, S2 Fig, Table 1). A protein interaction network analysis regrouping novel and previously known factors showed a high degree of connectivity (see below).

The fluorescence microscopy and multiplex PCR analyses for known and newly identified factors (S2 Fig) were confirmed by Southern blot analysis of \textit{mat1} content with the DdeI restriction enzyme (S3 Fig).

**Classification of genes related to mating-type switching by Southern blot**

Southern blots can be used to detect the imprint at \textit{mat1} and to determine whether rearrangements have occurred in the mating-type region. A DSB results from breakage at the fragile imprint site during DNA preparation [40]. As mentioned in the Introduction, the mating-type switching factors can be subdivided into three groups by Southern blot analysis of mutants, reflecting the molecular function of each factor. Class Ia is required for DSB formation at \textit{mat1}, Class Ib is involved in donor selection for mating-type switching or other steps in the use of the break, and Class II is required for processing the gene conversion intermediates [40]. The 23 strains selected for analysis were assayed by Southern blot (Fig 3). The analysis confirmed previous conclusions in the case of known factors, for instance \textit{swi3}Δ abolished DSB, and \textit{rad57Δ}, \textit{msh2Δ}, \textit{msh3Δ}, \textit{rad16Δ}, and \textit{pxd1Δ} caused high frequencies of rearrangements of the \textit{h}^+ type as expected for resolution-defective mutants [40]. The newly identified mating-type switching genes were assigned to Class Ib; \textit{elp6Δ}, \textit{swd1Δ}, \textit{spf1Δ}, \textit{brl2Δ}, \textit{pof3Δ} and \textit{ckb1Δ} strains were in that category together with \textit{swi2Δ}, \textit{cbp1Δ}, \textit{swi6Δ}, \textit{sir2Δ} and deletions of the Clr4 methyltransferase complex (CLRC), \textit{clr4Δ}, \textit{rik1Δ} and \textit{raf1Δ}, or Snf/Hdac-containing repressor complex (SHREC), \textit{clr1Δ}, \textit{clr2Δ} and \textit{clr3Δ}, subunits. As previously noticed for the \textit{swi6Δ} mutant [51] a rearrangement producing an 8.2 kb \textit{HindIII} fragment could be detected in several Class Ib mutants. The rearrangement could be a \textit{mat3:1} circle or a duplication of the mating-type region creating a \textit{mat3:1} cassette: \textit{mat1-L-mat2-P-K-mat3:1-L-mat2-P-K-mat3-M}. The \textit{mat3:1} cassette would not be amplified by the primers used to detect \textit{mat1} content by PCR. The \textit{swd2Δ} strain differed from the other mutants by showing a 9.9 kb \textit{HindIII} fragment hybridizing to the \textit{mat1} probe, however reconstruction of the strain produced a Class Ib mutant lacking this additional band and the reconstructed deletion allele was used in further analyses.

**Investigations of directionality defects in \textit{h}^{09} cells and in cells with mutated recombination enhancers**

In the \textit{h}^{09} mating-type region, the contents of the silent cassettes are swapped to \textit{mat2-M mat3-P} (Fig 4, S4 Fig). This arrangement results in inefficient heterologous switching and in a \textit{mat1} content biased towards \textit{mat1-M} [3]. How mutations affect this bias provides insights into the directionality of mating-type switching. For example, deletion of \textit{swi6} biases the \textit{mat1} content towards \textit{mat1-P} in \textit{h}^{09} cells, and towards \textit{mat1-M} in \textit{h}^{09} cells, consistent in both cases with preferred selection of \textit{mat3} as a donor [3]. This likely reflects a preferential use of the SRE3 recombination enhancer in \textit{swi6Δ} cells [23]. We created \textit{h}^{09} strains to test whether the newly identified Class Ib factors contribute to mating-type switching in the same or similar way as Swi6. Each deletion mutant was crossed with the \textit{h}^{09} strain PG4048. After the selection of recombinants, we analyzed four independent colonies of each \textit{h}^{09} deletion strain by multiplex PCR for \textit{mat1} content. As a control, colonies originating from spores of self-mating PG4048
cells were analyzed. As expected, PG4048 contained a greater proportion of M cells than P cells (a mean of 86% M cells; Fig 4). All mutations tested affected this ratio. The effects varied. During these analyses, we created a fresh deletion of swd2 to eliminate the rearrangement detected in the Bioneer mutant (9.9 kb band in Fig 3), as mentioned above, and confirmed that the observed directionality defects were not a result of the rearrangement.

A first group of factors comprised Swi6, CLRC subunits (Clr4, Rik1 and Raf1) and the histone deacetylase Sir2 (Fig 4). Mutations affecting CLRC or Sir2 produced nearly identical
values (around 70% P cells), similar to the loss of Swi6 (77% P cells). These mutants were also very similar to each other in the \(h^{09}\) background (around 20% P cells; Fig 2D). In the mating-type switching process, CLRC and its catalytic Clr4 subunit are believed to work by catalyzing the methylation of H3K9 in the \(mat2\)-\(mat3\) heterochromatic domain and creating binding sites for Swi6 [24, 52–55]. The role of Sir2 in the process might be to remove acetyl groups from H3K9 [46], thus facilitating heterochromatin formation [46, 56–58]. Indeed, the methylation of H3K9 and Swi6 association are reduced several fold in the mating-type region of \(sir2\Delta\) cells [46]. This is consistent with Sir2 acting upstream of CLRC and Swi6 through H3K9 deacetylation, without excluding that other actions of Sir2, e.g H3K4 deacetylation [59], might also be relevant to directionality.

The second group of mutants affecting mating-type switching in \(h^{09}\) cells were deletions of the genes for the ubiquitin E3 ligase Brl2, the Set1C subunits Swd1, Swd2 and Spf1, and the Elongator subunit Elp6 (Fig 4). These mutants resulted in a consistent increase in \(mat1\)-P content in \(h^{09}\) cells, from ~20% in wild-type background to ~35% in each of the three mutants. While not as pronounced as for Swi6 or CLRC mutants, the increase occurred to the same degree in all four isolates examined in each case. These mutants were unexpected because it has been reported that \(set1\Delta\) has no effect on mating-type switching [60]. We examined each component of Set1C (Set1, Swd1, Swd2, Spf1, Ash2, Shg1 and Sdc1 [61]) by iodine staining and multiplex PCR of mutants (Fig 5A–5D). Consistent with the previous report [60], deletion of \(set1\) or other subunit genes showed little effect on iodine staining of either \(h^{09}\) or \(h^{09}\) colonies (Fig 5A and 5B). However, monitoring \(mat1\) content clearly showed that individual gene deletions biased switching toward \(mat3\)-P in \(h^{09}\) cells and resulted in a correlated
increased use of mat3-M in $h^{90}$ cells for six Set1C subunits (Fig 5C and 5D). This trend is similar to mutations in the H3K9 methylation pathway, although not to the same amplitude (Fig 4). Interestingly, the iodine staining level of $set1\Delta$ colonies differed between $h^{90}$ and $h^{09}$ in spite of similar cell-type ratios (39% P cells in $h^{90}$ and 36% in $h^{09}$). Due to a different switching pattern, P and M cells might be less evenly mixed in $h^{09}$ colonies compared with $h^{90}$. This would lead to less efficient mating and spore formation in $h^{09}$ even though the cell-type bias is only a little more pronounced than in $h^{90}$. To investigate the functionality of each SRE element in $set1\Delta$ cells, we analyzed directionality in SRE element mutants (Fig 5E–5H). Deletion of $set1^{+}$ did not significantly affect mat1 content in $2\times SRE2$ cells (where the SRE3 element is replaced Fig 5. Analysis of mating-type switching directionality of Set1C mutants. (A, B) Spore formation of mutants in each Set1C subunit was assayed by exposure of colonies to iodine vapor. $h^{90}$ strains are shown in (A) and $h^{09}$ stains are shown in (B). (C, D, E) Quantification of mat1 content estimated by multiplex PCR. The relative P band intensity in each lane (P/(P+M)) was calculated from the data shown in S5 Fig for the $h^{90}$ strains shown in (C); from S5 Fig for the $h^{09}$ strains shown in (D) and from S5 Fig for the strains with mutated SRE elements shown in (E–H). (E) $2\times SRE2$ strains (mat2-P-SRE2 mat3-M-SRE2) were derived from the $set1^{+}$ strain TP126; (F) $2\times SRE3$ strains (mat2-P-SRE3 mat3-M-SRE3) from TP303; (G) SRE3 from TP3; and (H) SRE2A from TP8. Four $set1\Delta$ isolates are shown in each case. (C–H) Data are represented as mean ± SD. Two-tailed paired Student’s t test was used to compare the mean of each sample to cntl, *$p < 0.01$; **$p < 0.005$; n.s., not significant.

https://doi.org/10.1371/journal.pgen.1007424.g005
with SRE2) (Fig 5E) or in SRE3Δ cells (Fig 5G). However, in populations of 2×SRE3 cells (where the SRE2 element is replaced with SRE3) deletion of set1 caused a small increase in M cells (31% P cells in 2×SRE3 set1Δ compared with 36% P cells in 2×SRE3 set1+) (Fig 5F). In the case of SRE2Δ, donor choice was more strongly biased towards mat3-M in set1Δ cells (6% P cells) than in set1+ cells (13% P cells) (Fig 5H). This suggests that Set1C normally inhibits the choice of mat3-M-SRE3 in M cells. It has similarly been observed that deletion of swi6 causes virtually no change in donor choice in the 2×SRE2 and SRE3Δ backgrounds, where SRE2 keeps being used, but decreases use of SRE3 in SRE2Δ cells (5% P cells in SRE2Δ swi6Δ compared with 16% P cells in SRE2Δ swi6Δ) [23]. Loss of the Brl2 ubiquitin ligase resulted in phenotypes similar to mutations compromising Set1C (Figs 4 and 5). Thus, like Swi6 and CLRC, Set1C and Brl2 appear to favor use of the SRE2 recombination enhancer over SRE3 when both enhancers are present, perhaps by inhibiting the use of SRE3, to result in balanced switching.

A third group of mutants displayed a variegated phenotype (clr1Δ, clr2Δ, clr3Δ, ckb1Δ, pof3Δ and cbp1Δ; Fig 4), with the proportion of P cells varying between independent cultures. In some isolates, the proportion of P cells was nearly wild-type whereas in others it was similar to the swi6Δ mutant. These phenotypes were not caused by rearrangements in the mating-type region (S4 Fig). Clr1, 2 and 3 are subunits of SHREC, the Snf2-histone deacetylase repressor complex [62]. Clr3 participates in the recruitment of Clr4 to the mating-type region, but in its absence a Clr3-independent, RNAi-dependent pathway accomplishes this function to some extent [63]. Clr3 localizes to three regions in the mating-type region, which are close to mat2-P (RII), cenH and mat3-M (RIII), respectively [62, 64]. In the cenH region, the heterochromatin platform is likely established by RNAi-mechanisms; on the other hand, at the RIII site, it is established by an RNAi-independent mechanism [63, 65, 66]. The clonal variations observed in clr1, clr2 and clr3 h09 mutants might reflect these distinct pathways of heterochromatin establishment similar to position effect variegation [67]. Heterochromatin would be partially formed and inherited in some clonal populations of the mutant strains but not in others, leading to populations differentially proficient for switching. It is also known that the CK2-dependent phosphorylation of Swi6 mediates Clr3 recruitment to centromeric regions [68], possibly accounting for the Ckb1 defects observed here.

**Swi6-dependent and independent pathways of mating-type switching**

To further address the mechanisms of mating-type switching, we analyzed the protein-protein interaction network linking newly identified and previously known mating-type switching factors in the STRING database (Table 1) [69]. The obtained interaction network correlates strongly with categories established by Southern blotting and phenotypic classification (Fig 6A). Among the newly identified factors, six subunits of Set1C and Brl2 are connected to Class Ib factors. While Pof3, Ckb1 and Elp6 show no direct interaction with Class Ib factors in the STRING analysis (Fig 6A), several studies have reported that Pof3 plays a role in heterochromatin silencing [70–72] and Ckb1 phosphorylates Swi6 [68]. Elp6 is an orthologue of a part of the six-subunit Elongator complex (Elp1-6) in *S. cerevisiae* [73, 74]. Elp3 also passed the initial screening (S2 Table), however the other subunits of Elongator complex did not. The main cellular function of Elongator is thought to be in tRNA modification, but Elongator has also been proposed to acetylate histones [75–77].

We tested the hypothesis that some factors might act through Swi6 by performing an epistasis analysis. Double mutants combining swi6Δ with each candidate gene deletion were constructed and four independent colonies were analyzed by multiplex PCR for each of them (Fig 6B and 6C).
The mating-type switching phenotypes of the *swi6Δ clr4Δ* and *swi6Δ sir2Δ* double mutants were quite similar to the single deletions of *swi6*, *clr4* or *sir2* (Figs 2D, 4, 6B and 6C). This is consistent with CLRC and Sir2 being required for heterochromatin establishment and Swi6 recruitment at the *mat* locus (Fig 7).

Double mutants combining *swi6Δ* with *swd1Δ*, lacking a Set1C subunit, or *clr3Δ*, lacking a SHREC subunit, also displayed a phenotype quite similar to the *swi6Δ* single mutant (Fig 6B and 6C). This indicates that Set1C and SHREC work in the Swi6 pathway. A previous study has shown that *set1Δ* does not affect Swi6 localization or silencing of a *ura4* marker gene at *cenH* in the mating-type region [60] but other assays have found that Set1C subunits

---

**Fig 6.** Protein interaction network and genetic interactions. (A) An interaction network of newly identified and previously known mating-type switching factors (Table 1) was obtained from the STRING database (v10.0). The proteins are represented by nodes. Red and blue nodes show factors detected in this screen. White and black nodes show known mating-type switching factors that were not detected in this screen, either because the gene deletions were not in the library, or due to the set thresholds or human error. The line thickness represents the strength of the association (confidence > 0.6). It has been suggested that the presence of the DSB at mat1 is lethal in deletion mutants of *rad51*, *rad52* and *rad54* [36, 38]). (B, C) Genetic interactions between *swi6* and the identified Class Ib genes. mat1 content was quantified for the indicated double mutants with the *h90* (B) or *h09* (C) mating-type region. The relative P band intensities (P/(P+M)) were calculated from gels shown in S6 Fig. Red bars represent means ± SD.

https://doi.org/10.1371/journal.pgen.1007424.g006
participate in the repression of heterochromatic loci including the mating-type region [78]. This latter effect might be related to the occurrence of switching defects in Set1C mutants. Set1C may control Swi6 localization in a site-specific manner such as at SRE3 (Fig 5).

Fig 7. Mating-type switching model. (A) Donor selection controlled by heterochromatin. In the presence of heterochromatin, mat2-P is preferred over mat3-M in M cells due to an increased accessibility of SRE2 to switch-promoting binding factors and to a reduced accessibility of SRE3. In the absence of heterochromatin, SRE3 can stimulate recombination by Swi6-independent binding of Swi6. In P cells, the inhibition to select SRE3 is released. (B) Model of mating-type switching regulated by heterochromatin formation. The histone deacetylases Sir2 and SHREC remove histone acetylation (green). CLRC methylates H3K9 (pink). Swi6 binds to methylated H3K9 and nucleates heterochromatin. CK2 phosphorylates Swi6 (red). Cbp1 binds at specific regions in the mat locus. Clr3 (SHREC) is recruited to phosphorylated Swi6 and Cbp1 binding site. Set1C might affect heterochromatin at SRE3. The Swi2-5 complex binds to Swi6 and Rad51, which regulates mating-type switching directionality. Pof3, Elp6 and Brl2 might also affect switching by histone modification.

https://doi.org/10.1371/journal.pgen.1007424.g007

participate in the repression of heterochromatic loci including the mating-type region [78]. This latter effect might be related to the occurrence of switching defects in Set1C mutants. Set1C may control Swi6 localization in a site-specific manner such as at SRE3 (Fig 5).

Donor preference in swi6Δ ckb1Δ cells indicated that swi6Δ is also epistatic to ckb1Δ even though phenotypes could only be assigned in the h09 background due to apparently high rates of rearrangement in the h09 background. Nevertheless, the data suggest that Swi6 phosphorylation by Ckb1 [68] is important for switching directionality controlled by Swi6.

More complex epistatic relationships were observed for the remaining mutants, brl2Δ, pof3Δ, cbp1Δ, elp6Δ, and swi2Δ, when these mutations were combined with swi6Δ (Fig 6B and 6C). The predominant mating-type had a tendency to vary between isolates, particularly with the h09 mating-type region, and rearrangements occurred. Double mutants combining brl2Δ
and swi6Δ showed a mat1-M bias apparently even more pronounced than for the swi6Δ single mutant in h^90, while in h^09 two swi6Δ brl2Δ isolates were similar to swi6Δ and two had more balanced mat1 contents. Populations of h^90 swi6Δ pof3Δ cells showed biases similar to the h^90 swi6Δ single mutant for three isolates, whereas the fourth isolate was biased towards P cells rather than M cells. Populations of h^09 swi6Δ pof3Δ cells had varied ratios of P and M cells, and two isolates were rearranged. The switching bias for swi6Δ cbp1Δ was similar to swi6Δ with the h^90 mating-type region (Fig 6B), but two strains in four differed from swi6Δ with the h^09 mating-type region (Fig 6C). This phenotype may be caused by Swi2 expression level, which is controlled by Cbp1 [26, 31]. Rearrangements in h^90 swi6Δ elp6Δ and h^09 swi6Δ elp6Δ mutants precluded analysis. These observations suggest that both Swi6-dependent and -independent pathways control switching directionality by Brl2, Pof3, and Cbp1. Finally, swi2Δ swi6Δ double mutants differed from swi6Δ in both h^90 and h^09. It has been reported that Swi2 can localize to SRE3 in the absence of Swi6 [22, 23, 27]. The more balanced cell populations in swi6Δ swi2Δ mutants are probably caused by loss of Swi6-independent function of Swi2.

In summary, our observations suggest that the factors, Clr4, Sir2, Swd1 and Clr3 probably work in the same pathway as Swi6, but Brl2, Pof3, Cbp1, and Swi2 have an effect on donor selection through Swi6-dependent and -independent mechanisms. Frequent DNA rearrangements in Class Ib mutants (Fig 3) and in double mutants with swi6Δ indicate that histone modifications not only direct donor choice, but also facilitate resolution steps or prevent unequal sister chromatid exchanges between cassettes.

**Mating-type switching model by regulation of Swi6 association with the mating-type region**

We propose a model summarizing how each factor identified in this study might participate in the donor selection mechanism (Fig 7). In this model, the heterochromatin structure in M cells favors the cassette adjacent to SRE2 as a donor while structural changes in mutants and in P cells favor SRE3 [23]. In addition, chromatin structure prevents selection of the cassette adjacent to SRE3 in M cell (Fig 7A). It has been reported that SRE2 can facilitate donor choice efficiently not only in M cells but also in P cells whereas SRE3 is more active in P cells than in M cells [23]. These data indicate that the inhibition of donor choice does not affect SRE2.

Mating-type switching is initiated by a site-specific imprint during replication. In the replisome, Swi1-Swi3, Pol1, and Mrcl are required for the imprint [16, 40]. One of the novel switch factors identified here is the ubiquitin ligase component Pof3. Pof3 interacts with the replisome, in an Mrcl- and Mcl1-dependent manner [71, 79]. However, rather than participating in imprint formation, we found that Pof3 affects donor selection. Pof3 is also required for heterochromatic silencing near mat3 [70]. We speculate that both effects are brought about by the Pof3-mediated degradation of replisome components [80] or of Ams2, a cell cycle-regulated transcription factor for histone genes [81] that also mediates long range chromosomal interactions [82] and interacts with Raf1, a component of CLRC [83]. Thus, Pof3 would couple the deposition of new histones and their modification by CLRC. During S phase, partly as a result of new histones deposition onto replicated DNA, Swi6 and H3K9me2 levels decrease at silenced loci [84, 85]. A wave of H3K9 acetylation, observed in other organisms in front of the replication fork [86], might further weaken heterochromatin. The current search expands on previous work to show that enzymatic complexes required for the restoration of heterochromatin, both NAD⁺-dependent and -independent HDACs and CLRC, are necessary for donor selection. Remarkably, lack of Sir2 or of a CLRC subunit phenocopied the swi6Δ deletion in both h^90 and h^09 cells (Figs 2D and 4) while the loss of SHREC components resulted in variegated phenotypes. We take these differences as reflecting the different substrate specificities.
and recruitment mechanisms of the two HDACs to heterochromatic regions [57, 87]. In both cases, our epistasis analysis with the Swi6 mutant points to defects in Swi6 recruitment. Our search also identified Cbp1 and CK2, both of which are thought to recruit Clr3 to heterochromatin regions [64, 68]. Cbp1 also controls expression of the swi2 gene and the cell-type specific protein isoform it produces, together with the M-specific protein Mc [26, 31].

A novel and intriguing outcome of our study is that multiple subunits of Set1C and the E3 ubiquitin ligase Brl2 are required for accurate donor selection. Set1C catalyzes the methylation of H3K4. A role in heterochromatin appears paradoxical, given that methylated H3K4 is strongly associated with expressed genes. One possibility is that Set1C regulates the expression of Swi2, central effector of switching directionality, or of other switching factors. RNA profiling analysis has revealed that switching genes are expressed to similar levels in wild type and individual Set1C mutants [87], however more subtle effects such as shifts in transcription initiation have not been ruled out. In addition, S. pombe Set1C appears directly required for silencing at various locations [78]. In the mating-type region, all subunits except for Shg1 are required for silencing of the cenH repeat. Evidence has also emerged for roles in meiotic recombination [88, 89] even though the effects of H3K4 methylation on recombination have been hard to unravel due to the prevalence of that modification genome-wide [90]. Here, we favor a simple model where Set1C affects donor choice directly. This could be through local, possibly temporally restricted methylation of H3K4 at SRE3 that would either act as such or by preventing H3K4 acetylation. Brl2 is part of HULC that catalyzes the ubiquitylation of histone H2B (H2Bub) [61, 91, 92]. H2Bub stabilizes the interaction of Set1 with chromatin in vitro [93]. The single brl2Δ deletion affected mat1 content similar to the deletion of Set1C components (Figs 2, 4 and 5). These connections and phenotypic similarities indicated that Set1C and HULC might co-operate to choose a correct donor. (Figs 4 and 6B). However, the phenotypes of two in four independent colonies of h90 swi6Δ brl2Δ strain differed from h90 swi6Δ swd1Δ (Fig 6C). Brl2 is also known to interact with Nse5, which is a part of the structural maintenance of chromosome 5/6 (Smc5-6) holocomplex [94, 95]. It may have multiple functions in mating-type switching.

Following the cell-type specific deposition of Swi6, Swi2-Swi5 localizes to SRE2 by interaction with Swi6 in M cells [22, 23, 27]. Together with the inhibited use of SRE3, this regulated recruitment of Swi2-Swi5 effectively directs the Rad51 strand-exchange protein to initiate homologous recombination at the proper cassette, providing an increasingly well understood model for the effects of chromatin structure on recombination.

Materials and methods

Yeast strains, strain construction, and strain manipulations

S. pombe strains were generated and propagated according to standard protocols [96]. They were manipulated with a Singer RoToR plate-handling robot (Singer Instruments) for high throughput screens. To test for mating-type switching defects by fluorescence analysis, a query strain (PG4045: h90 (Blp1)::LEU2 leu1::ura4+-[mfn3p-YFP]-[map2p-CFP] ura4-D18 ade6-M216) was mated to the Bioneer gene deletion library (h90 leu1-32 ura4-D18 ade6-210 or 216, ORFΔ::kanMX4). Mating was performed on SPA plates supplemented with 200 mg/l leucine, 100 mg/l uracil, and 100 mg/l adenine. Cells were allowed to mate and sporulate at 30˚C for two days. The mating plates were then moved to 42˚C for three days to eliminate vegetative cells. Following heat treatment, spores were transferred onto YES plates with 100 mg/l G418 and allowed to germinate and divide for three days at 30˚C. To select for h90 progeny, cells were then transferred from the YES plates to MSA plates with 100 mg/l G418 and 100 mg/l adenine and grown for a further three days at 30˚C. This scheme selects for (Blp1)::LEU2,
tightly linked to the h^90 region, for ura4^+, tightly linked to the fluorescent reporters, and for kanMX4 that marks each ORF deletion. Single colonies were isolated from bulk recombinants by streaking cells onto MSA plates containing G418 and adenine, incubated for three days at 30˚C. The sdc1 deletion strain (h^+ sdc1::Kan^r ade6-M21? leu1-32 ura4-D18) was obtained from the National BioResource Project (NBRP ID: FY23769, strain name: P1-1G).

**Fluorescence microscopy**

Single colonies of recombinants obtained as described above were inoculated into 50 µL MSA medium supplemented with 100 mg/l adenine and grown for two days at 30˚C in 96 well plates. Cells were then diluted 24 times into MSA medium with adenine and grown for ~20 hr at 30˚C. Sixty µl cell suspensions diluted 15 times with MSA medium with adenine were transferred to 384 well microplates with clear bottom (CellCarrier-384 ultra, Perkin Elmer). The fluorescence of cells was measured using an Opera high-content screening microscope (Perkin Elmer). The following settings were used [Filter sets: Camera 1: 475/50 for CFP signals, Camera 2: 540/75 for YFP signals, Camera 3: 690/50 for bright field, Light source: 405/488/635]. Twelve images were taken for each well, for a total of ~200 cells per strain. The proportion of P cells was then calculated using the Acapella software program (PerkinElmer). Selected strains were imaged again using a Delta Vision Elite microscope (GE Healthcare).

**Iodine staining**

Cells were plated onto MSA medium supplemented with 100 mg/l adenine, allowed to form single colonies, and exposed to iodine vapors.

**Multiplex PCR**

*S. pombe* cells were propagated in 2 mL liquid YES cultures at 30˚C to saturation. Genomic DNA was prepared from wild-type and mutant cells as described [97]. The genomic DNA concentration was measured using QuantiFlor One dsDNA Dye System (Promega) and 4 µL genomic DNA (1.25–5.0 ng/µL) in TE was added to 16 µL PCR reaction reagent (total 20 µL) to perform multiplex PCR to determine the genetic content of the *mat1* or *mat3* locus. The primers used were FAM-MT1 (5’-AAATAGTGGGTAGCGTGAAGG-3’) at 400 nM, MP1 (5’-ATCTATCCAGGATGGCAAGGTG-3’) at 200 nM and MM1(5’-GGGAACCCGCTGATAATTCTTGG-3’) at 200 nM (S3 Fig). The 5’ end of FAM-MT1 and FAM-MT3 were modified with 6-carboxyfluorescein (FAM). To reduce non-specific PCR products, 400 nM heat-stable RecA protein from a thermophilic bacterium, *Thermus thermophiles*, and 400 µM ATP were included in the PCR reaction buffer (10 mM Tris-HCl pH 8.3, 50 mM KCl, 2.5 mM MgCl_2) [98]. The following amplification program was used: 2 min at 94˚C—27 x [30 s at 94˚C —30 s at 55˚C—1 min at 72˚C]—5 min at 72˚C. PCR fragments corresponding to *mat1-P* and *mat1-M* alleles were resolved on 5% polyacrylamide gels. Fluorescence was detected and quantified using Typhoon FLA9500 (GE Healthcare) and ImageQuant (GE Healthcare).

**Barcode sequencing**

Each gene knockout in the Bioneer collection contains 'up-tag' and ‘down-tag’ sequences that provide a unique barcode for each knockout. To confirm the identity of the mutants identified in our screen, we amplified the KanMX4 region using the U1 primer (5’-CGCTCCCGGC TACCTGCA-3’) and D1 primer (5’-TTGGCTGTCGCGAAGGGATG). The PCR products were then sequenced using cpn1 (5’-CGTCTGAGGGAGGCCTTT-3’) to read the up-tag.
and cpc300 (5'-AGACCGATAACGATCTTGGCC-3') to read the down-tag. The results were compared with the barcode list.

Southern blots

S. pombe cells were propagated in 16 mL liquid cultures (YES) at 30°C to pre-saturation and genomic DNA for Southern blots was prepared as described above. Genomic DNA was digested with HindIII to classify the mating-type switching defective genes according to DSB formation or presence of rearrangements in the mating-type region (Fig 3), or with DdeI to assay mat1 content (S3 Fig). The digested samples were electrophoresed in 0.7% agarose gels. The probe to analyze mat1 content was a PCR product made with GTO-1369 (5’- GAGCCTACTGTTAATATAAACTATG-3’) and GTO-1370 (5’-CCTTCAACTACTCTCTCCTTCTTTCCCTACCC-3’), corresponding to the centromere-proximal DdeI-NsiI fragment [23]. The probes to classify the mutants were 10.4 kb HindIII fragments containing mat1-P or mat1-M.

Supporting information

S1 Fig. Outline of screen. The Bioneer collection of S. pombe haploid deletion strains (V5) was mated with PG4045 on SPA plates in an arrayed format using a high-throughput robot (Singer Inst.). Spores were selected, germinated, and G418-resistant progeny that were also prototrophic for leucine (selecting for h90 mating-type region) and uracil (selecting for cell-type specific fluorescent reporters) were obtained, colony purified, re-arrayed, and examined by a combination of fluorescence microscopy with a high throughput Opera microscope (all strains), iodine staining of colonies (subset of strains with unclear fluorescence output), and multiplex PCR (subset of strains with potential mating-type switching defects obtained in the first screens).

S2 Fig. Analysis of mating-type switching related genes by fluorescence microscopy and iodine staining assays. (A) Merged channels for wild-type h90 strain (cntl) and two mutants. The 15 mutants shown in (B, C) were identified by fluorescence microscopy or iodine staining analysis in the screen outlined in S1 Fig. (B) Repeat of cell-type quantification using a DeltaVision Elite microscope (GE Healthcare). (C) Iodine staining of strains with the indicated gene deletions.

S3 Fig. Effects of culture conditions and detection method (multiplex PCR versus Southern blot) on mat1 content measurements. (A, B) Representation of the mat1 region showing (A) priming sites used for multiplex PCR and (B) the restriction sites and probe (DdeI-NsiI fragment) used for the Southern blots in (E). (C) Location of primers and probe complementarity on h90, h+M, duplicated mating-type region (mat1-L-mat2-P-K-mat3:1-L-mat2-P-K-mat3-M), and mat2:1 or mat3:1 circles. (D) 30 μL of saturated YES pre-cultures (2 ml each) were used to inoculate 20 mL YES cultures that were then propagated until late exponential phase. DNA was extracted from both the 2 ml pre-cultures and the 20 ml cultures and analyzed by multiplex PCR. (E) DNA preps from 20 mL YES cultures were analyzed by Southern blot taking advantage of the size difference between a mat1-P and mat1-M fragment in DdeI digests. Measurements by multiplex PCR and Southern blots are compared.

S4 Fig. Effect of Class Ib mutants identified in the screen on mating-type switching in the h90 strain. (A) Multiplex PCR analysis of the mutants shown in Fig 4. The content of mat1 was
estimated by quantification of P- and M-specific band intensities. (B) Southern blot analysis using HindIII digests of genomic DNA and a 10.4 kb mat1 HindIII fragment as probe.

S5 Fig. Multiplex PCR analysis of mating-type switching directionality in Set1C subunit mutants and SRE element mutants. (A, B) Multiplex PCR analysis of the mutants shown in Fig 5C and 5D and quantification of mat1 content estimated from P- and M-specific band intensities. The relative P band intensity in each lane (P/(P+M)) was calculated from (A) h90 and (B) h09. (C-F) Epistasis analysis by multiplex PCR analysis for the Set1 and SRE elements mutants shown in Fig 5E–5H. The relative P band intensity (P/(P+M)) was calculated for each lane. (C) 2×SRE2 (mat2-P-SRE2 mat3-M-SRE2) strains were derived from strain TP126; (D) 2×SRE3 (mat2-P-SRE3 mat3-M-SRE3) strains were derived from strain TP303; (E) SRE3Δ from TP75 and (F) SRE2Δ from TP8.

S6 Fig. Multiplex PCR analysis of double mutants. Multiplex PCR analysis of the mutants shown in Fig 6B and 6C. The content of mat1 was estimated by quantification of P- and M-specific band intensities. N.D. = Not-detected.

S1 Table. List of strains used in crosses.

S2 Table. Bioneer mutants showing potentially biased mating-type ratios in fluorescence screen and their characterization by multiplex PCR for mat1 content and by barcode sequencing.

S3 Table. Bioneer mutants with altered iodine staining phenotypes and their characterization by multiplex PCR for mat1 content and by barcode sequencing.

S4 Table. Bioneer mutants excluded from the analysis.

Acknowledgments

We thank N. Steen, P. Brøgger, M. M. Jørgensen, S. Brown, A. E. Chavez, B. Argunhan, H. Tsubouchi and Y. Murayama for valuable discussions and suggestions, J. Verhein-Hansen and Y. Umamoto for technical assistance. We are thankful to the National BioResource Project for providing strains. Imaging data from the Opera microscope were collected at the Center for Advanced Bioimaging (CAB) Denmark, University of Copenhagen, with the help of Nynne Christensen. We thank the Biomaterials Analysis Division, Tokyo Institute of Technology for sequence analysis.

Author Contributions

Conceptualization: Takahisa Maki, Hiroshi Iwasaki, Geneviève Thon.

Data curation: Takahisa Maki.

Formal analysis: Takahisa Maki, James E. Haber, Hiroshi Iwasaki, Geneviève Thon.

Funding acquisition: James E. Haber, Hiroshi Iwasaki, Geneviève Thon.
Investigation: Takahisa Maki, Naoto Ogura.

Methodology: Takahisa Maki, Geneviève Thon.

Project administration: Hiroshi Iwasaki, Geneviève Thon.

Resources: Hiroshi Iwasaki.

Supervision: Hiroshi Iwasaki, Geneviève Thon.

Validation: Takahisa Maki.

Visualization: Takahisa Maki.

Writing – original draft: Takahisa Maki.

Writing – review & editing: James E. Haber, Hiroshi Iwasaki, Geneviève Thon.
