Abstract

We study the computational complexity of ARRIVAL, a zero-player game on n-vertex switch graphs introduced by Dohrau, Gärtner, Kohler, Matoušek, and Welzl. They showed that the problem of deciding termination of this game is contained in $\text{NP} \cap \text{coNP}$. Karthik C. S. recently introduced a search variant of ARRIVAL and showed that it is in the complexity class PLS. In this work, we significantly improve the known upper bounds for both the decision and the search variants of ARRIVAL.

First, we resolve a question suggested by Dohrau et al. and show that the decision variant of ARRIVAL is in $\text{UP} \cap \text{coUP}$. Second, we prove that the search variant of ARRIVAL is contained in CLS. Third, we give a randomized $O(1.4143^n)$-time algorithm to solve both variants.

Our main technical contributions are (a) an efficiently verifiable characterization of the unique witness for termination of the ARRIVAL game, and (b) an efficient way of sampling from the state space of the game. We show that the problem of finding the unique witness is contained in CLS, whereas it was previously conjectured to be $\text{FPSPACE}$-complete. The efficient sampling procedure yields the first algorithm for the problem that has expected runtime $O(c^n)$ with $c < 2$.

1 Introduction

Variants of switch graphs have applications and are studied for example in combinatorics and in automata theory (cf. [11] and the references therein). Dohrau et al. [5] introduced ARRIVAL, a natural computational problem on switch graphs, which they informally described as follows:

Suppose that a train is running along a railway network, starting from a designated origin, with the goal of reaching a designated destination. The network, however, is of a special nature: every time the train traverses a switch, the switch will change its position immediately afterwards. Hence, the next time the train traverses the same switch, the other direction will be taken, so that directions alternate with each traversal of the switch.

Given a network with origin and destination, what is the complexity of deciding whether the train, starting at the origin, will eventually reach the destination? [5]

The above rather straightforward question remains unresolved. Dohrau et al. [5] showed that deciding ARRIVAL is unlikely to be NP-complete (by demonstrating that it is in \( \text{NP} \cap \text{coNP} \)), but it is currently not known to be efficiently solvable.

To determine whether the train eventually reaches its destination, it is natural to consider a run profile, i.e., the complete transcript describing how many times the train traversed each edge. Dohrau et al. [5] presented a natural integer programming interpretation of run profiles called switching flows, which have the advantage of being trivial to verify. The downside of switching flows is that they do not guarantee to faithfully represent the number of times each edge has been traversed; a switching flow might contain superfluous circulations compared to a valid run profile. Nevertheless, Dohrau et al. [5] proved that the existence of a switching flow implies that the train reaches its destination, and thus a switching flow constitutes an NP witness for ARRIVAL.

The \( \text{coNP} \) membership was shown by an insightful observation about the structure of switch graphs. Specifically, the train reaches its destination \( d \) if and only if it never enters a node from which there is no directed path to \( d \). The railway network can thus be altered so that all such vertices point to an additional “dead-end” vertex \( \bar{d} \). The \( \text{coNP} \) witness is then simply a switching flow from the origin to the dead-end \( \bar{d} \).

Given that the decision variant of ARRIVAL is in \( \text{NP} \cap \text{coNP} \), it is natural to study the search complexity of ARRIVAL in the context of total search problems with the guaranteed existence of a solution, i.e., within the complexity class TFNP (which contains the search analogue of \( \text{NP} \cap \text{coNP} \)). Total search problems are classified into subclasses of TFNP using the methodology proposed by Papadimitriou [13] that clusters computational problems according to the type of argument assuring the existence of a solution. Karthik C. S. [14] noticed that the search for a switching flow is a prime candidate to fit into the hierarchy of TFNP problems. He introduced S-ARRIVAL, a search version of ARRIVAL that seeks a switching flow to either the destination \( d \) or the dead-end vertex \( \bar{d} \), and showed that it is contained in the complexity class PLS [10] of total problems amenable to local search.
Fearnley et al. [6] recently studied multiple variants of reachability games on switch graphs and as one of their results gave a lower bound on the complexity of deciding ARRIVAL. Specifically, they showed that ARRIVAL is NL-hard.

1.1 Our Results

One of the open problems suggested by Dohrau et al. [5] was whether deciding the termination of ARRIVAL is contained in $\text{UP} \cap \text{coUP}$ (recall that $\text{UP}$ is a subclass of NP such that for each YES-instance there is a unique certificate). Recall that given a railway network with an origin $o$ and a destination $d$, the transcript of the route of the train captured in the run profile from $o$ to $d$ (if it exists) is unique. We show that it is possible to efficiently decide whether a switching flow corresponds to a run profile, which provides a positive answer to the above question and places ARRIVAL inside $\text{UP} \cap \text{coUP}$. We similarly also improve the upper bound on the search complexity of ARRIVAL: We show that S-ARRIVAL is contained in the complexity class $\text{CLS}$. Daskalakis and Papadimitriou [4] introduced $\text{CLS}$ to classify problems that can be reduced to local search over continuous domains. $\text{CLS}$ contains multiple important search problems such as solving simple stochastic games, finding equilibria in congestion games, and solving linear complementarity problems on P-matrices. For all of these problems, as well as for S-ARRIVAL, we currently do not have a polynomial time algorithm, and they are not known to be complete for some subclass of $\text{TFNP}$.

We establish the containment in $\text{CLS}$ through a reduction to END-OF-METERED-LINE (EOML), a total search problem that was recently introduced by Hubáček and Yogev [9] who also showed that it is in $\text{CLS}$. In EOML we are given a source in a directed graph with vertices of in-degree and out-degree at most one, and the task is to find a sink or a source different from the given trivial source. The access to the graph is given locally via information about the successor and predecessor of each vertex together with its distance from the trivial source (for the formal definition see Definition 18).

Our result makes it unlikely for S-ARRIVAL to be $\text{PLS}$-hard, which was one of the possibilities suggested by the containment in $\text{PLS}$ shown by Karthik C. S. [14]. This is due to known black-box separations among subclasses of $\text{TFNP}$ [12, 2], which suggest that $\text{CLS}$ is a proper subclass of $\text{PLS}$. Note that our reduction from S-ARRIVAL to END-OF-METERED-LINE results in instances with a significantly restricted structure: the END-OF-METERED-LINE graph consists only of a single path and many isolated vertices. We believe that this structure may in future work be used to show that S-ARRIVAL is contained in $\text{FP}$.

Our reduction from S-ARRIVAL to END-OF-METERED-LINE also implies that we can use an algorithm by Aldous [1] to solve S-ARRIVAL. The algorithm is randomized and runs in $\mathcal{O}(2^{n/2}\text{poly}(n))$ expected time on switch graphs with $n$ vertices. This is the first algorithm with expected runtime $\mathcal{O}(c^n)$ for $c < 2$. (A trivial $\mathcal{O}(2^n\text{poly}(n))$ time algorithm can be obtained by following the path of the train through the network.) Aldous’ algorithm, in fact, solves any problem in $\text{PLS}$. It samples a large number of candidate solutions and then performs a local search from the best sampled solution. The advantage of our reduction is that the resulting search space for END-OF-METERED-LINE is small enough to make Aldous’ algorithm useful, unlike in the previous reduction by Karthik C. S. [14] that showed containment in $\text{PLS}$.

Fearnley et al. [7] recently gave a reduction from $\text{P}$-matrix linear complementarity problems (PLCP) to END-OF-METERED-LINE. As in our case for ARRIVAL, this implies that Aldous’ algorithm can be used to solve PLCP. In fact this gives the fastest known randomized algorithm for PLCP, running in expected time $\mathcal{O}(2^{n/2}\text{poly}(n))$ for input matrices of dimension $n \times n$. Fearnley et al. do not make this observation themselves, but it is
straightforward to check that their reduction also gives an efficient representation of the
search space. Although Aldous’ algorithm is very simple, it non-trivially improves the best
runtime of algorithms for multiple problems. We believe that this way of applying Aldous’
algorithm is a powerful technique that will produce additional results in the future.

1.2 Technical remarks

Recall that a switching flow is a run profile with additional superfluous circulations compared
to the valid run profile. Our main technical observation is a characterization of switching
flows that correspond to the valid run profile. Given a switch graph \( G \) and a switching
flow \( f \), we consider the subgraph \( G^* \) induced over the railway network by the “last-used”
edges; for every vertex \( v \), we include in \( G^* \) only the outgoing edge that was, according to the
switching flow, used by the train last time it left from \( v \). Note that such last-used edges can
be efficiently identified simply by considering the parity of the total number of visits at every
vertex. When \( f \) is a valid run profile, then it is straightforward to see that the subgraph \( G^* \)
is acyclic. We show that this property is in fact a characterization, i.e., any switching flow
for which the induced graph \( G^* \) is acyclic must be a run profile. Given that this property
is easy to check, we can use it to efficiently verify run profiles as UP witnesses. (The coUP
witness is then a run profile to the dead-end at \( \bar{d} \).)

For our reduction from S-Arrival to End-Of-Metered-Line we extend the above
observation to partial switching flows that are not required to end at the destination. The
vertices of the End-Of-Metered-Line graph created by our reduction correspond to partial
switching flows in the S-Arrival instance. The directed edges connect partial run profiles
to their natural successors and predecessors, i.e., the partial run extended or shortened by a
single step of the train. Any switching flow that does not correspond to some partial run
profile is an isolated vertex in the End-Of-Metered-Line graph. Finally, the trivial source
is the empty switching flow, and the distance from it can be computed for any partial run
simply as the number of steps taken by the train so far. Given that there is only a single path
in the resulting End-Of-Metered-Line graph and that its sink is exactly the complete
run, we get that the unique solution to the End-Of-Metered-Line instance gives us a
solution for the original instance of S-Arrival.

To make the reduction efficiently computable, we need to address the verification of
partial run profiles. As it turns out, partial run profiles can be efficiently verified using the
graph \( G^* \), in a similar way to complete run profiles discussed above. The main difference is
that the graph of last-used edges for a partial run profile can contain a cycle, as the train
might visit the same vertex multiple times on its route to the destination. However, we show
that there is at most one cycle in \( G^* \), which always contains the current end-vertex of the
partial run. The complete characterization of partial run profiles (which covers also full run
profiles) is given in Lemma 9, and the formal reduction is described in Section 4.2.1.

Finally, we show that every partial run profile is uniquely determined by its last-used
edges and its end-vertex. This limits the size of the search space for the EOML instances
that are produced by our reduction, which allows us to efficiently use Aldous’ algorithm [1]
to solve Arrival and S-Arrival.

2 Preliminaries

In the rest of the paper we use the following standard notation. For \( k \in \mathbb{N} \), we denote by \([k]\)
the set \( \{1,\ldots,k\} \). For a graph \( G = (V,E) \), we reserve \( n = |V| \) for the number of vertices.
The basic object that we study are switch graphs, as defined by Dohrau et al. [5].
A natural witness for termination of the Run procedure considered in previous work (e.g. \cite{5}) is a switching flow. We extend the definition of a switching flow to allow for partial switching flows that do not necessarily end in the desired destination \(d\).

**Definition 3 (partial switching flow, end-vertex).** Let \(G = (V, E, s_0, s_1)\) be a switch graph. For \(o, d \in V\), we say that \(f \in \mathbb{N}^{2n}\) is a switching flow from \(o\) to \(d\) if the following two conditions hold.

- Kirchhoff’s Law (flow conservation):
  \[
  \forall v \in V : \sum_{e = (u,v) \in E} f_e - \sum_{e = (v,w) \in E} f_e = [v = d] - [v = o],
  \]
  where \([\cdot]\) is the indicator variable of the event in brackets.

- Parity Condition:
  \[
  \forall v \in V : f_{s_1(v)} \leq f_{s_0(v)} - f_{s_1(v)} + 1.
  \]

Kirchhoff’s law means that \(o\) emits one unit of flow, \(d\) absorbs one unit of flow, and at all other vertices, in-flow equals out-flow. If \(d = o\), we have a circulation.

Given an instance \((G = (V, E, s_0, s_1), o, d)\) of ARRIVAL, we say that \(f\) is a switching flow if it is a switching flow from \(o\) to \(d\). A vector \(f \in \mathbb{N}^{2n}\) is called a partial switching flow iff \(f\) is a switching flow from \(o\) to \(v\) for some vertex \(v \in V\). We say that \(v\) is the end-vertex of the partial switching flow. We denote the end-vertex of \(f\) by \(v_f\).

---

\(^5\) Whenever \(s_0(v) = s_1(v)\) for some vertex \(v \in V\) we depict them as multiple edges in figures.
Definition 4 ((partial) run profile). A run profile is the switching flow \( r \) returned by the algorithm Run (Algorithm 1) upon termination. A partial run profile is a partial switching flow corresponding to some intermediate value of \( r \) in the algorithm Run (Algorithm 1).

Observation 5 (Dohrau et al. [5, Observation 1]). Each (partial) run profile is a (partial) switching flow.

Observation 6. An end-vertex \( v_f \) of a switching flow \( f \) is computable in polynomial time.

Proof. It is sufficient to determine which vertex has a net in-flow of one.

3 The Complexity of Run Profile Verification

Dohrau et al. [5] proved that it is possible to efficiently verify whether a given vector is a switching flow. In this section we show that we can also efficiently verify whether a switching flow is a run profile. Combining this with the results by Dohrau et al. [5], we prove that the decision problem of Arrival is in \( \text{UP} \cap \text{coUP} \) (see Section 4.1) and that the search problem of Arrival lies in the complexity class \( \text{CLS} \) (see Section 4.2). As outlined in Section 1.2, our approach for verification of run profiles is based on finding a cycle in a natural subgraph of the railway network \( G \) defined below. Specifically, we consider the subgraph of \( G \) that contains only the last visited outgoing edge of each vertex, i.e., every vertex has out-degree at most one.

Definition 7 \((G_f^*)\). Let \((G = (V,E,s_0,s_1),o,d)\) be an instance of Arrival, and let \( f \in \mathbb{N}^{2n} \) be a partial switching flow. We define a graph \( G_f^* = (V,E^*) \) as follows

\[
E^* = \left\{ s_0(v) : \forall v \in V \text{ s.t. } f_{s_0}(v) \neq f_{s_1}(v) \right\} \cup \left\{ s_1(v) : \forall v \in V \text{ s.t. } f_{s_0}(v) = f_{s_1}(v) > 0 \right\}.
\]

Observation 8. Given a partial switching flow \( f \), the graph \( G_f^* \) can be computed in polynomial time.

Lemma 9. A partial switching flow \( f \) is a partial run profile iff \( f_{s_0(d)} = f_{s_1(d)} = 0 \) and one of the following two conditions holds:

1. There exists no cycle in \( G_f^* \).
2. There exists exactly one cycle in \( G_f^* \) and this cycle contains the end-vertex of \( f \).

The main idea of the proof is based on the following fact: a switching flow \( f \) which is not a run profile must contain a circulation (as shown by Dohrau et al. [5]). Let \( f \) be a switching flow that we get from a run profile \( r \) by adding some flows on cycles, then the last added circulation (the last added cycle) must form a cycle in the corresponding graph \( G_f^* \). On the
other hand, a cycle containing the end-vertex is formed in $G_f$ whenever the train arrives to a previously visited vertex. An illustration of the graph $G_f$ at consecutive steps of the algorithm Run, with the corresponding evolution of the end-vertices and cycles, is given in Figure 1.

The complete proof of Lemma 9 is provided in the full version [8].

Lemma 10. It is possible to verify in polynomial time whether a vector is a run profile.

Proof. We can check that a vector $f$ is a switching flow in polynomial time due to Dohrau et al. [5]. The construction of the graph $G_f$ is polynomial by Observation 8. Lemma 9 gives us a polynomial time procedure to check if $f$ is also a run profile as it is sufficient to check if $G_f$ contains more than one cycle or whether it has a cycle not containing the end-vertex. This check can be done by a simple modification of the standard depth-first search on $G_f$.

4 The Computational Complexity of Arrival

In this section we use our efficient structural characterization of run profiles from Lemma 9 to improve the known results about the computational complexity of Arrival. Specifically, we show that the decision version of Arrival is in $\text{UP} \cap \text{coUP}$ and the search version is in CLS.

4.1 The Decision Complexity of Arrival

Our upper bound on the decision complexity of Arrival follows directly from the work of Dohrau et al. [5] by application of Lemma 10.

Theorem 11. Arrival is in $\text{UP} \cap \text{coUP}$.

Proof. The unique UP certificate for a YES-instance of Arrival is the run profile $r$ returned by the algorithm Run. Clearly, for each YES-instance there exists only one such vector $r$ and $r$ does not exist for NO-instances. By Lemma 10, we can determine whether a candidate switching flow $r$ is a run profile in polynomial time.

The coUP membership follows directly from the reduction of NO-instances of Arrival to YES-instances of Arrival as suggested by Dohrau et al. [5]. The reduction adds to the original graph $G$ a new vertex $\bar{d}$, and for each vertex $v \in V$ such that there is no directed path from $v$ to the destination $d$, the edges $s_0(v)$ and $s_1(v)$ are replaced with edges $(v, \bar{d})$. This alteration of the original switch graph can be performed in polynomial time. Dohrau et al. [5] proved that the train eventually arrives either at $d$ or $\bar{d}$. The unique coUP witness for Arrival is then a run profile from $o$ to the dead-end $\bar{d}$.

4.2 The Search Complexity of Arrival

The search complexity of Arrival was first studied by Karthik C. S. [14], who introduced a total search variant of Arrival as follows.

Definition 12 (S-Arrival [14]). Given a switch graph $G = (V, E, s_0, s_1)$ and a pair of vertices $o, d \in V$, define a graph $G'$ as follows:
1. Add a new vertex $\bar{d}$.
2. For each vertex $v$ such that there is no directed path from $v$ to $d$, replace edges $s_0(v)$ and $s_1(v)$ with edges $(v, \bar{d})$.
3. Edges $s_0(d), s_1(d), s_0(\bar{d})$, and $s_1(\bar{d})$ are self-loops.

The problem S-Arrival is to find a switching flow in $G'$ either from $o$ to $d$ or from $o$ to $\bar{d}$.
The above Definition 12 is motivated by the proof of membership in \( \text{NP} \cap \text{coNP} \) by Dohrau et al. [5]. Namely, in order to ensure that a solution for S-Arrival always exists, it was necessary to add to the switch graph \( G \) the dead-end vertex \( d \).

Note that our method for efficient verification of run profiles from Lemma 10 allows us to define a more natural version of S-Arrival directly on the graph \( G \) without any modifications. Instead of relying on the dead-end vertices, we can use the fact that a partial run profile with an edge that was visited for \( 2^n + 1 \) times is an efficiently verifiable witness for NO-instances of Arrival.

**Definition 13 (S-Arrival - simplified).** Given a switch graph \( G = (V, E, s_0, s_1) \) and a pair of vertices \( o, d \in V \), the S-Arrival problem asks us to find one of the following:

1. a run profile \( r \in \mathbb{N}^{[2^n]} \) from \( o \) to \( d \), or
2. a run profile \( r \in \mathbb{N}^{[2^n]} \) from \( o \) to any \( v \in V \) such that
   \[ r_{(u,v)} = 2^n + 1, \text{ where } u \text{ is the last vertex visited by the train before it reached the end-vertex } v \text{ of } r, \text{ and} \]
   \[ r_{e'} \leq 2^n \text{ for all } e' \neq (u,v). \]

The correspondence of the above version of S-Arrival to the original one follows formally from the following lemma.

**Lemma 14 (Karthik C. S. [14, Lemma 1]).** For any \( G = (V, E, s_0, s_1) \) and a pair of vertices \( o, d \in V \). Let \( r \) be a run profile (thus \( v_r = d \)), then \( r_e \leq 2^n \) for each edge \( e \in E \).

To argue membership of our version of S-Arrival in TFNP, we need to show that both types of solutions in Definition 13 can be verified efficiently. Solutions of the first type are simply run profiles, and we have already shown that they can be verified in polynomial time in Lemma 10. In order to be able to verify solutions of the second type, it remains to argue that for any partial run profile, the immediate predecessor of its end-vertex can be determined in polynomial time.

**Lemma 15.** Let \( r \) be a partial run profile after \( R \geq 1 \) steps and \( u \) be the vertex visited by the train at step \( R - 1 \). Then

1. either \( u \) is the unique predecessor of \( v_r \) in \( G^*_r \), or
2. there is a single cycle in \( G^*_r \) containing \( v_r \) and \( u \) is the predecessor of \( v_r \) on this cycle.

**Proof.** First, note that if \( u \) is the end-vertex one step before \( v_r \) becomes the end-vertex then \( G^*_r \) must contain the edge \((u, v_r)\), as it is the last edge used by the train to leave \( u \). Thus, in the first case (when \( v_r \) has only one predecessor in \( G^*_r \)) the immediate predecessor of \( v_r \) in the partial run \( r \) is unambiguously given by the only predecessor of \( v_r \) in \( G^*_r \).

For the second case we show that \( G^*_r \) contains a directed cycle \( C \) (containing the end-vertex \( v_r \)) and \( u \) is unambiguously given by the predecessor of \( v_r \) in \( G^*_r \) that lies on \( C \). We find the cycle \( C \) by constructing the longest possible directed path \( c_0 = v_r, c_1, \ldots, c_k \) in \( G^*_r \) without repeating vertices. Note that it cannot happen that \( c_k \) has no outgoing edge in \( G^*_r \). Otherwise, \( r \) would have two different end-vertices \( v_r \) and \( c_k \) (as having no outgoing edge in \( G^*_r \) means that the train has never left this vertex). By Lemma 9, the directed edge from \( c_k \) has to end in the end-vertex \( v_r \), or else there would be a cycle in \( G^*_r \) that avoids \( v_r \).

The algorithm RUN takes \( R \) steps to generate the run profile \( r \), i.e., \( \sum_{e \in E_r} r_e = R \). Let \( t_r : V \to \{0,1,\ldots, R - 1\} \) be the function returning the last step after which a vertex was left by the train in the partial run profile \( r \). Observe that, except for the edge through which
the train arrived to \( \nu_r \), it holds for all edges \((x, y) \in G^*_r\) that \( t_r(x) < t_r(x) + 1 \leq t_r(y)\). However, the above inequality cannot hold for all edges on the cycle \( C \), and thus \( C \) has to contain the last used edge and the train had to be in \( c_k \) at step \( R - 1 \).

**Observation 16.** S-Arrival from Definition 12 reduces to simplified S-Arrival from Definition 13.

**Proof.** Given a solution of the second type of the simplified S-Arrival, i.e., the long run profile, we can get a run profile \( r \) to \( d \) in polynomial time. For each vertex \( u \) we can determine whether there is an oriented path from it to the destination \( d \), and if there is no such path we set \( r_{s_0(v)} = r_{s_1(v)} = 0 \). We compute the end vertex \( \nu_r \) and set \( s_0(\nu_r) = 1 \). All other components of \( r \) are set according to the original solution of the simplified S-Arrival.

### 4.2.1 S-Arrival is in CLS

Karthik C. S. [14] showed that S-Arrival is contained in the class PLS. We improve this result and prove that S-Arrival is in fact contained in CLS. As a by-product, we also obtain a randomized algorithm for S-Arrival with runtime \( \mathcal{O}(1.4143^n) \) which is the first algorithm for this problem with expected runtime \( \mathcal{O}(e^n) \) for \( e < 2 \).

The class of total search problems that are amenable to “continuous” local search was defined by Daskalakis and Papadimitriou [4] using the following canonical problem.

**Definition 17** (CLS [4]). CLS is the class of total search problems reducible to the following problem called CLOPT.

Given two arithmetic circuits \( f : [0, 1]^3 \rightarrow [0, 1]^3 \) and \( p : [0, 1]^3 \rightarrow [0, 1] \), and two real constants \( \varepsilon, \lambda > 0 \), find either a point \( x \in [0, 1]^3 \) such that \( p(f(x)) \leq p(x) + \varepsilon \) or a pair of points \( x, x' \in [0, 1]^3 \) certifying that either \( p \) or \( f \) is not \( \lambda \)-Lipschitz.

Instead of working with CLOPT, we use as a gateway for our reduction a problem called End-Of-Metered-Line (EOML) which was recently defined and shown to lie in CLS by Hubáček and Yogev [9].

**Definition 18** (End-Of-Metered-Line). Given circuits \( S, P : \{0, 1\}^m \rightarrow \{0, 1\}^m \), and \( V : \{0, 1\}^m \rightarrow [2^n] \cup \{0\} \) such that \( P(0^m) = 0^m \neq S(0^m) \) and \( V(0^m) = 1 \), find a string \( x \in \{0, 1\}^m \) satisfying one of the following:

1. either \( P(S(x)) \neq x \) or \( S(P(x)) \neq x = 0^m \)
2. \( x \neq 0^m \) and \( V(x) = 1 \)
3. either \( V(x) > 0 \) and \( V(S(x)) - V(x) \neq 1 \) or \( V(x) > 1 \) and \( V(x) - V(P(x)) \neq 1 \).

The circuits \( S, P \) from Definition 18 implicitly represent a directed graph with vertices labelled by binary strings of length \( m \), where each vertex has both out-degree and in-degree at most one. The circuit \( P \) represents the predecessor and the circuit \( S \) represents the successor of a given vertex as follows: there is an edge from a vertex \( u \) to a vertex \( v \) iff \( S(u) = v \) and \( P(v) = u \). Finally, the circuit \( V \) can be thought of as an odometer that returns the distance from the trivial source at \( 0^m \) or value 0 for vertices lying off the path starting at the trivial source. The task in End-Of-Metered-Line is to find a sink or a source different from the trivial one at \( 0^m \) (the solutions of the second and of the third type in Definition 18 ensure that \( V \) behaves as explained above).

We are now ready to present our reduction from S-Arrival to End-Of-Metered-Line.

---

6 The inequality does not hold for \( \nu_r \), since \( t(\nu_r) \) has not been updated to the time \( R \) yet.
Theorem 19. S-Arrival can be reduced to End-Of-Metered-Line, and thus it is contained in CLS.

Proof. Let \((G, o, d)\) be an instance of S-Arrival. We construct an instance of EOML that contains a vertex for each candidate partial switching flow over the switch graph \(G\), i.e., for each vector with \(2n\) coordinates and values from \([2^n + 1] \cup \{0\}\). The EOML instance will comprise of a directed path starting at the initial (empty) partial run profile \(0^{2^n}\). Each vertex on the path has an outgoing edge to its consecutive partial run profile. Any vertex that does not correspond to a partial run profile becomes a self-loop. Finally, the valuation circuit \(V\) returns either the number of steps in the corresponding partial run profile or the zero value if the vertex does not correspond to a partial run profile. Formal description of the circuits \(S, P\), and \(V\) defining the above EOML graph is provided in the full version [8]. A polynomial bound on the size of the circuits \(S, P\), and \(V\) follows directly from Observation 8 (computing \(G^*\)), Lemma 10 (testing whether a given vector is a partial run profile), Observation 6 (computing the end-vertex), and Lemma 15 (computing the previous position of the train).

Lemma 9 and Lemma 15 imply that the EOML graph indeed consists of a single directed path and isolated vertices with self-loops. By the construction of \(V\) (it outputs the number of steps of the train), there are no solutions of the second or the third type (cf. Definition 18). Thus, the EOML instance has a unique solution which has to correspond to a run profile in the original S-Arrival instance or to a partial run profile certifying that the train ran for too long (see the second type of solution in Definition 13). \(\blacksquare\)

5 An \(O(1.4143^n)\) Algorithm for S-Arrival

Consider any problem that can be put into the complexity class PLS, i.e., can be reduced to the canonical PLS-complete problem LocalOpt (see also [14, Definition 1]):

Definition 20 (LocalOpt). Given circuits \(S: \{0, 1\}^m \to \{0, 1\}^m\), and \(V: \{0, 1\}^m \to [2^m] \cup \{0\}\), find a string \(x \in \{0, 1\}^m\) such that \(V(x) \geq V(S(x))\).

Aldous [1] introduced the following simple algorithm that can be used to solve LocalOpt: pick \(2^{m/2}\) binary strings uniformly and independently at random from \(\{0, 1\}^m\), and let \(x_{\text{max}}\) be the selected string that maximizes the value \(V(x)\). Starting from \(x = x_{\text{max}}\), repeatedly move to the successor \(S(x)\), until \(V(x) \geq V(S(x))\). He showed that the expected number of circuit evaluations performed by the algorithm before finding a local optimum is at most \(O(m2^{m/2})\). Note that in the case of EOML it is possible that all sampled solutions are isolated vertices in the EOML graph. In this case the \(0^m\) string has the best known value, and the search is started from there.

In the case of S-Arrival, the PLS membership proof of Karthik C. S. constructs the circuits for successor and valuation with \(O(n^2)\) input bits [14, Theorem 2]; the EOML instance constructed in Theorem 19 – proving CLS and in particular PLS membership – yields circuits of \(O(n^2)\) input bits as well. This number is too high to yield a randomized algorithm of non-trivial runtime.

This number of \(O(n^2)\) input bits comes from the obvious encoding of a partial run profile: each of the \(2n\) edges has a nonnegative integer flow value of at most \(2^n + 1\). But in fact, a terminating run has at most \(n2^n\) partial run profiles, as no vertex-state pair \((v, s_{\text{curr}})\) can repeat in Algorithm 1. In other words, a partial run profile \(f\) is determined by its end-vertex \(v_f\) as well as the positions of all switches at the time of the corresponding visit of \(v_f\). This means that a partial run profile can be encoded with \(n + \log_2 n\) bits, and if we had a PLS or CLS membership proof of S-Arrival with circuits of this many inputs only, we could solve S-Arrival in time \(O(\text{poly}(n) \times 2^{n/2})\).
Next, we show that such membership proofs indeed exist. For this, we show that the above encoding (of a partial run profile by an end-vertex and the positions of all switches) can be efficiently decoded: given an end-vertex and the positions of all switches, we can efficiently compute a unique candidate for a corresponding partial run profile. The resulting encoding and decoding circuits can be composed with the ones in Theorem 19 to obtain PLS and CLS membership proofs with circuits of \( n + \log_2 n \) input bits, and hence yield a randomized algorithm of runtime \( O(\text{poly}(n) \times 2^{n/2}) = O(1.4143^n) \), as explained above.

### 5.1 Decoding Partial Run Profiles

We work with instances of S-Arrival as in Definition 12, i.e., there is always a run profile either to \( d \) or to \( \bar{d} \). This is without loss of generality [5, 14].

**Definition 21.** Let \( G = (V, E, s_0, s_1) \) be a switch graph, and let \( o, d, \bar{d} \in V \) be as in Definition 12. The parity of a run profile \( f \in \mathbb{N}^{2n} \) is the vector \( p_f \in \{0, 1\}^{n-2} \) defined by \( p_e = f_{s_0(v)} - f_{s_1(v)} \in \{0, 1\}, v \in V \setminus \{d, \bar{d}\} \).

Note that we do not care about (the parity of) the switches at \( d \) and \( \bar{d} \), since the algorithm stops as soon as \( d \) or \( \bar{d} \) is reached.

Here is the main result of this section. For a given target vertex \( t \in V \) and given parity \( p \), there is exactly one candidate for a partial run profile from \( o \) to \( t \) with parity \( p \). Moreover, this candidate can be computed by solving a system of linear equations.

**Lemma 22.** Let \( (G, o, d, \bar{d}) \) be an instance of S-Arrival, let \( t \in V \) and \( p \in \{0, 1\}^{n-2} \). Then there exists exactly one vector \( f \in \mathbb{R}^{2(n-2)} \) such that the following conditions hold.

**Kirchhoff’s Law (flow conservation):**

\[
\forall v \in V \setminus \{d, \bar{d}\}: \sum_{e=(u,v) \in E} f_e - \sum_{e=(v,w) \in E} f_e = [v = t] - [v = o] \tag{1}
\]

where \([\cdot]\) is the indicator variable of the event in brackets.

**Parity Condition:** \( p_f = p \), i.e.,

\[
\forall v \in V \setminus \{d, \bar{d}\}: f_{s_0(v)} - f_{s_1(v)} = p_v. \tag{2}
\]

Before we prove Lemma 22, let us draw a crucial conclusion: The unique partial run profile \( f \in \mathbb{N}^{2n} \) with end-vertex \( t \) and parity \( p \) (if such \( f \) exists – note that we are only guaranteed a real-valued \( f \)) necessarily satisfies (1) and (2). Hence, we may use Lemma 22 to get the entries \( f_e \) for all edges except the ones leaving \( d \) and \( \bar{d} \). Only if all the entries are nonnegative and integral and satisfy (1) at \( d \) and \( \bar{d} \) (under \( f_{s_0(d)} = f_{s_1(d)} = f_{s_0(\bar{d})} = f_{s_1(\bar{d})} = 0 \)) do we have a candidate for a partial run profile. Hence, there is a unique candidate, and given \( t \) and a \( p \), this candidate can be efficiently found.

**Proof of Lemma 22.** Set \( m = 2(n-2), V' = V \setminus \{d, \bar{d}\} \) and let \( A \in \mathbb{Z}^{m \times m} \) be the coefficient matrix of the linear system (1), (2) in the variables \( f_v \). We show that \( A \) is invertible.

Let \( q \in \mathbb{R}^m \) be the vector such that \( q_{(v,s_i(v))} = -1 \) if \( s_i(v) = d \) and \( q_{(v,s_i(v))} = 0 \) otherwise. We show that \( q \) can be expressed as a linear combination of the rows of \( A \) in a unique way, from which invertibility of \( A \) and the statement of the lemma follow.

Let us use coefficients \( \lambda_v \) for each \( v \in V' \) for the rows corresponding to the flow conservation constraints (1), and coefficients \( \mu_v \) for each \( v \in V' \) for the rows corresponding to the parity constraints (2). The column of \( A \) corresponding to variable \( f_{(v,s_i(v))} \), has a \(-1\) entry from the flow conservation constraint at \( v \), and a \(1\) entry (if \( i = 0 \)) or a \(-1\) entry (if
i = 1) from the parity constraint at v. If \( s_i(v) \neq d, \bar{d} \), there is another 1 entry from the flow conservation constraint at \( s_i(v) \). All other entries are zero. The equations that express \( q \) as a linear combination of rows of \( A \) are therefore the following.

\[
\forall v \in V' : -\lambda_v + \mu_v + \lambda_{s_0(v)} \cdot [s_0(v) \neq d, \bar{d}] = q_{(v, s_0(v))},
\]

\[
\forall v \in V' : -\lambda_v + \mu_v + \lambda_{s_1(v)} \cdot [s_1(v) \neq d, \bar{d}] = q_{(v, s_1(v))}.
\]

Or equivalently:

\[
\lambda_v - \mu_v = \begin{cases} 
\lambda_{s_0(v)}, & \text{if } s_0(v) \neq d, \bar{d} \\
1, & \text{if } s_0(v) = d \\
0, & \text{if } s_0(v) = \bar{d} 
\end{cases}, \quad \forall v \in V', \tag{3}
\]

\[
\lambda_v + \mu_v = \begin{cases} 
\lambda_{s_1(v)}, & \text{if } s_1(v) \neq d, \bar{d} \\
1, & \text{if } s_1(v) = d \\
0, & \text{if } s_1(v) = \bar{d} 
\end{cases}, \quad \forall v \in V'. \tag{4}
\]

We now show that there are unique coefficients \( \lambda_v, \mu_v \) satisfying these equations. Let us define \( \lambda_d = 1 \) and \( \lambda_{\bar{d}} = 0 \). Adding corresponding equations of (3) and (4) then yields

\[
\lambda_d = 1, \quad \lambda_{\bar{d}} = 0, \quad \lambda_v = \frac{1}{2} \left( \lambda_{s_0(v)} + \lambda_{s_1(v)} \right), \quad \forall v \in V'.
\]

These are exactly the equations for the vertex values in a \textit{stopping simple stochastic game} on the graph \( G \) with only average or degree-1 vertices and sinks \( d \) and \( \bar{d} \) (stopping means that \( d \) or \( \bar{d} \) are reachable from everywhere which is exactly what we require in a switch graph). Condon proved that these values are unique [3]. This also determines the \( \mu_v \)'s uniquely. ▶

### 6 Conclusion and Open Problems

We showed that candidate run profiles in \textsc{Arrival} can be efficiently verified due to their structure. This allowed us to improve the known upper bounds for the search complexity of \textsc{Arrival} and \textsc{S-Arrival}. Here we mention some natural questions arising from our work.

- Are there any non-trivial graph properties that make \textsc{Arrival} or \textsc{S-Arrival} efficiently solvable? Given that we currently do not know of any polynomial time algorithm for \textsc{Arrival} on general switch graphs, we could study the complexity of \textsc{Arrival} on some interesting restricted classes of switch graphs.

- Are there other natural problems in UP ∩ coUP such that their corresponding search variant is reducible to \textsc{EOML}? Does \textsc{End-Of-Metered-Line} capture the computational complexity of any \textsc{TFNP} problem with unique solution? Fearnley et al. [7] recently gave a reduction from the \textsc{PLCP} to \textsc{EOML}. Given that \textsc{Arrival} and \textsc{PLCP} can be both reduced to \textsc{EOML}, yet another intriguing question is whether there exists any reduction between the two.

- As mentioned in Section 1.1, the reduction from \textsc{PLCP} to \textsc{EOML} by Fearnley et al. [7] implies that \textsc{PLCP} can be solved faster with Aldous’ algorithm [1] than with any other known algorithm. It would be interesting to see whether Aldous’ algorithm can similarly give improved runtimes for other problems than \textsc{Arrival} and \textsc{PLCP}.
