ABSTRACT

Sequence-specific DNA binding recruits transcription factors (TFs) to the genome to regulate gene expression. Here, we perform high resolution mapping of CEBPs proteins to determine how sequence dictates genomic occupancy. We demonstrate a fundamental difference between the sequence repertoire utilized by CEBPs in vivo versus the palindromic mental difference between the sequence repertoire that dictates genomic occupancy. We demonstrate a fundamental difference between the sequence repertoire utilized by CEBPs in vivo versus the palindromic sequence preference reported by classical in vitro models, by identifying a palindromic motif at $<1\%$ of the genomic binding sites. On the native genome, CEBPs bind a diversity of related 10 bp sequences resulting from the fusion of degenerate and canonical half-sites. Altered DNA specificity of CEBPs in cells occurs through heterodimerization with other bZip TFs, and approximately 40% of CEBP-binding sites in primary human cells harbor motifs characteristic of CEBP heterodimers. In addition, we uncover an important role for sequence bias at core-motif-flanking bases for CEBPs and demonstrate that flanking bases regulate motif function across mammalian bZip TFs. Favorable flanking bases confer efficient TF occupancy and transcriptional activity, and DNA shape may explain how the flanks alter TF binding. Importantly, motif optimization within the 10-mer is strongly correlated with cell-type-independent recruitment of CEBPβ, providing key insight into how sequence sub-optimization affects genomic occupancy of widely expressed CEBPs across cell types.

INTRODUCTION

Sequence-specific DNA binding by transcription factors (TFs) is fundamental to the establishment and maintenance of gene programs that drive cell function in health and disease (1,2). The genomic distribution of TFs at enhancers and promoters defines the framework by which these proteins orchestrate temporal and spatial regulation of gene expression (3,4). The genomic landscape of TF-binding sites (TFBSs) is organized by the non-random distribution of DNA recognition sequences, or motifs, that mediate recruitment of their cognate TFs (5). Consequently, defining the motif preferences employed by each TF and mapping the genomic locations of motifs are key to unlocking the basis for gene regulatory networks.

High-throughput approaches have facilitated the identification of TFBSs both in vitro and in vivo (6–8). Protein binding microarrays (PBMs) and high-throughput in vitro selection (HT-SELEX) have determined the specificities of hundreds of isolated TFs from multiple species (9,10). Alternatively, chromatin immunoprecipitation combined with next generation sequencing (ChIP-seq) has been employed extensively to locate where TFs occupy the native genome and to interrogate motifs from overrepresented sequences in ChIP-seq peaks. DNA accessibility (11–13) as well as contextualizing factors including DNA shape (14–18), DNA methylation (19–21), neighboring TF interaction (22,23) and altered sequence specificity due to heterodimer formation between related TFs (24) constrain and reshape how TFBSs are utilized in native genomes. Collectively, these variables help explain why TFs occupy only a small fraction of candidate motifs in the genome (25).

Contrary to the strong sequence dependence of TF binding in vitro, it has been suggested that TFs are recruited independently of their cognate sequences at many ChIP-seq peaks either through indirect protein-protein interaction (tethering) (23,26–29) or through recognition of DNA shape (30,31). Coupled with the observation that motif scores fail to differentiate between bound versus unbound genomic sequences (17,32,33), the question of what consti-
tutes the minimal sequence determinants for TFBSs in vivo has become increasingly uncertain. Fortunately, new experimental approaches are providing avenues to address this question. High resolution (20–50 bp) mapping of bound genomic sequences has been facilitated by the development of ChIP with lambda exonuclease digestion and sequencing (ChIP-exo) (34). Close discrimination of bound motifs can revise and improve recognition sequences (35,36) and resolve dimeric versus monomeric binding (37,38). In parallel, comparison of bound and unbound motifs in biochemical assays of TF binding to histone-free genomic DNA is providing further insight into the native sites that are sufficient to mediate occupancy (39–42). Uniting these approaches has the potential to bridge major gaps in our understanding of the relationship between TF sequence specificity, motif occurrence and occupancy at native genomic sites.

CEBP TFs are particularly interesting in terms of how DNA-binding specificity defines genomic occupancy for two key reasons. As lineage determining TFs in several tissues (43–46), CEBPs may function as pioneer factors that overcome the inhibitory effects of chromatin, and thus defining their sequence specificity may be instructive as to whether a relationship exists between binding site affinity and TF occupancy in the genome. In addition, CEBPs can bind DNA as both homodimers and heterodimers (46), and their ability to target different sequence motifs through heterodimerization with other bZip family members (24,40,47–49) may enable the utilization of a broad repertoire of motifs to control a variety of gene expression programs (50). Indeed, CEBPs occupy tens of thousands of sites in primary cells and tissues (25,51–53), however degenerate ChIP-seq motifs obscure the importance of sequence determinants for binding site selection.

Here, we report the high-resolution mapping of CEBP-binding sites in the human and mouse genomes using ChIP-exo. We find that CEBPs occupy a large repertoire of sequences in vivo defined by the fusion of canonical and degenerate CEBP half sites. Positive selection for the nucleotide composition observed within the core motif reflects altered sequence specificity of CEBP homo- versus heterodimers. We demonstrate the importance of the CEBP 10-mer motif by identifying an optimal sequence that is prevalently bound independent of cell type, suggesting that it forms a high-affinity-binding site that overrides chromatin context. Moreover, we reveal a critical role for negative sequence selection, i.e. the exclusion of a particular base, at the first and last position of the 10-mer. Negative selection for specific flanking nucleotide pairs is a general feature shared by multiple bZIP TF motifs, and the distinction between favorable and unfavorable motif contexts correlates with changes in DNA shape. We illustrate the functional importance of flanking base composition by showing that natural genetic variation from single nucleotide polymorphisms (SNPs) that introduce non-permissive flanking bases leads to strain-specific CEBP occupancy in mice. Collectively, these findings provide an expanded motif definition for CEBP that can be generalized to the broader bZip family, and establish important relationships between motif optimization, genomic occupancy and transcriptional activity.

**MATERIALS AND METHODS**

**Animals and cell culture**

Animal experiments were reviewed and approved by the Institutional Animal Care and Use Committees of the University of Pennsylvania. Mice were kept under standardized conditions with water and food ad libitum in a pathogen-free animal facility. hMSCs were obtained from Lonza and maintained in low glucose Dulbecco’s modified Eagle’s medium supplemented with 10% fetal bovine serum and 2mM glutamine. hMSCs were used at passages 4 through 7.

**ChIP and ChIP-exo**

The following antibodies were used: CEBPα (sc-61, Santa Cruz), CEBPβ (sc-150, Santa Cruz), ATF4 (sc-200, Santa Cruz) and normal IgG (2729, Cell Signaling). ChIP in mouse liver was performed with a minimum of 3 individual mice per genotype. Primers for human and mouse ChIP are reported in Supplementary Table S1.

An Illumina-based ChIP-exo method (54) was performed with mouse liver and hMSCs. ChIP-exo in hMSCs was performed using approximately 7 million cells. ChIP-exo performed in vitro used binding conditions described previously for an in vitro cistromics assay modeled after ChIP-seq (40). Binding reactions (100 μl) were treated with 1% formaldehyde for 1 min at room temperature, quenched with 125 mM glycine for 5 min, and brought to 1 ml with binding buffer lacking DTT for immunoprecipitation. ATF4 and CEBPβ were expressed in BL21(DE3) Escherichia coli from pET30a vectors carrying an N-terminal His Tag and full-length CDNAs. Proteins were purified by Co2+ affinity chromatography and quantified by comparison with a BSA standard after SDS-PAGE. Approximately 25 μM ATF4 and/or 600 nM CEBPβ were present in the initial binding reaction of 100 μl. Library preparation was performed similarly to ChIP-exo with cells or tissue.

ChIP-exo data processing including initial peak calling of putative flanking borders and cross-correlation analysis of opposite-stranded peak pairs was performed as described previously (37). Biological replicates were performed for each liver and hMSC experiment, and peak pairs were scored as positive if called in each replicate, while downstream analyses utilized pooled data from both replicates. De novo motif search was performed within 50 bp windows from the top-1000 sites showing 15–30 bp spacing between opposite-stranded peak pairs using MEME-ChIP (55). Motif visualization emphasizing de-enriched bases was performed with REDUCE (56). ChIP-exo signal was visualized after scanning anchoring regions with the de novo motif PWM and identifying the site with maximum score in each region. Peaks from matching ChIP-seq data (40,57) served as anchoring regions for ChIP-exo experiments performed with tissue or cells. For in vitro ChIP-exo studies, opposite-stranded peak pairs of 15–30 bp were pooled, merged and extended to a 50 bp window.
Data analyses

**CEBPβ co-occupancy across cell types.** BAM files for CEBPβ and RNA Polymerase II ChIP-seq from 5 cell lines (A549, HelaS3, HepG2, IMR90, K562) were downloaded from ENCODE, and replicates were pooled into HOMER tag directories. Peak calling and peak merging for CEBPβ, as well as RPM quantification for all cell types (including hMSCs) was performed in HOMER. CEBPβ peaks had to meet a threshold of 1 RPM in at least one cell type. An average binding strength across all cells in which CEBPβ binding exceeds 1 RPM cutoff was calculated for each peak. A variable threshold defined as one quarter of this average value, or 1 RPM, whichever was lesser, was set as the criterion to determine occupancy in any given cell type. Thus the minimum cut-off for shared binding was 0.25 RPM, and any peak exceeding 4 RPM was scored as bound. Cell-type-specific peaks were enriched at least 4-fold relative to the cut-off.

Motif analysis of cell-type-specific versus cell-type-independent peaks. De novo motif analyses were performed on the subset of CEBPβ peaks used for the RNAPII genomic analyses using MEME-ChIP (55). The de novo PWMs were used to generate motif logos in the REDUCE Suite v2.2 (58). The most prevalent 8-mers within PWMs for enriched motifs were used to generate motif logos in the REDUCE Suite v2.2. RNA polymerase II analysis. The relationship between CEBPβ peaks and gene transcription was restricted to peaks annotated as either cell-type specific or occupied by CEBPβ across all 6 cell types and having RNA Polymerase II (RNAPII) enrichment of 1 RPM of higher. Additionally, to exclude peaks that exceeded the threshold for co-occupancy in all cell types but still exhibited differential CEBPβ binding, cell-type-independent peaks were subsetted to the 10% showing least variability in the ratio of the maximum to median RPM signal. Peaks meeting these criteria were mapped to the TSS of genes within 100 kb using BETA-minus tool in Cistrome (59). RNAPII occupancy was determined in HOMER and converted to RPKM. For each CEBPβ peak, only the two nearest expressed genes of 300 bp length or greater were included in the RNAPII analysis. GO terms and histograms of peak to TSS distances were obtained using GREAT 3.0 (60).

DNA shape analyses. DNA shape parameters were computed in R using the DNAshapeR tool from the Rohs lab (61). Heatmaps were generated in R. For the analysis involving PBM datasets (10), the raw data were downloaded from GEO (GSE53348; CREB = pTH5080; JUND = pTH5462; NFIL3 = pTH5082). Only probes with a single instance of the core bZip motif of interest and having at least 5 bp of flanking sequence present both upstream and downstream were used for DNA shape analyses. Probes with a motif match in the antisense direction were reverse complemented prior to shape analysis. Binding scores were computed as the difference of the mean signal intensity minus the mean background. Classification of bound versus unbound sequences was based on a threshold of ≥37% of the maximum score reported for a given dataset, corresponding to ~20 000 au (arbitrary units) for NFIL3 and CREB and 5000 au for JUND.

Motif analyses of other bZIP proteins. PWMs for enriched motifs in publicly available CREB, JUND, and NFIL3 ChIP-seq experiments were downloaded from the Cistrome Data Browser (GSM1873046; denovo_10, GSM935521; MC00371, GSM2574748; MS00337). PWMs were converted to ddG motif logos using the LogoGenerator script in REDUCE Suite v2.2.

Analysis of secondary candidate CEBP motifs. We mapped candidate 8-mers that matched the sequence any of the top 13 occupied CEBPβ sequences (see Figure 1E) in the hg19 genome using HOMER. Candidate 8-mers that occurred within an 11–200 bp window adjacent to a high confidence CEBPβ ChIP exo-bound (primary) site were included in the analyses in Figure 3C and D. ChIP exo-bound secondary sites were defined as having either a positive or negative peak pair exceeding 0.1 RPM read count and a summed RPM score of 0.15 RPM or greater. Heatmaps in Supplementary Figure S3C were ordered based on decreasing RPM exo strength (sum of positive and negative exo peak pair) at the secondary 8-mer sequence. Heatmaps visualizations were generated in Treeview. Polar bar graphs of flanking nucleotide pair frequency were generated using R.

Luciferase reporter assays

Synthetic bZip reporters were comprised of four repeats of each motif, separated by identical 18 bp spacer sequences. Unique flanking 5′ and 3′ extensions were added as PCR anchor points. Reporter cassettes totaled 163 bp or 159 bp for 10 bp or 9 bp bZip motifs, respectively. DNA cassettes were purchased as Ultramers from IDT, PCR amplified, and subcloned into the pGL4.24 vector using XhoI and BglII sites. Sequence for each multimerized motif is available in Supplementary Table S1. Sanger sequencing verified all plasmids. HEK293T were co-transfected with 320 ng of luciferase reporter construct, 40 ng of CMV-Renilla plasmid, and 40 ng of pCDNA3.1 or pCDNA3.1-Cebpβ, using 1.2 μl of Lipofectamine 2000 (Life Technologies) per well, in a reverse transfection protocol using 24 well plates. Cells were lysed in passive lysis buffer either 24 h (CRE reporter) or 48 hours (all other reporters) post-transfection. Relative luminescence (Firefly to Renilla ratio) was determined on a Biotek Synergy H1 microplate reader. Samples were assayed in a minimum of triplicates per biological condition.

Pyrosequencing

DNA (5% of ChIP samples or 0.5% of input DNA) was amplified by PCR using Phusion polymerase (NEB), a biotinyla...
RESULTS

CEBP proteins recognize a diversity of genomic sequences through a degenerate half site

To identify the genomic sequences targeted by CEBP TFs with high resolution in the native genome, we performed ChIP-exo in primary human mesenchymal stem cells (hMSCs) for CEBPβ as well as in mouse liver tissue for CEBPα and CEBPβ. The approach uses lambda exonuclease to trim ChIP DNA until a bound protein blocks further en-
zymatic activity (62). This creates 5’ borders on both DNA strands that are juxtaposed with the protein, manifested as opposite-stranded peak pairs on a genome browser, and achieves 20–50 bp resolution of DNA binding (34).

Opposite-stranded peak pairs annotate both canonical CEBPβ homodimer motifs and CEBPβ-sequences bound by the ATF4 heterodimer in hMSCs, demonstrating the resolving power of ChIP-exo (Figure 1A). Globally, CEBP peak pairs show an average distance distribution of 15–30 bp, with a predominant distance of 25 bp for CEBPβ and 27 bp for CEBPα (Figure 1B, Supplementary Figure S1A). Motif analysis reveals exclusive enrichment of an 8-mer core sequence comprised of a degenerate half site (TKnn) fused to a CEBP half site (GCAA) (Figure 1C, Supplementary Figure S1B). Ordered peak pairs flank this motif at a majority of ChIP-seq peaks (Figure 1D, Supplementary Figure S1C), indicating that CEBPs occupy the genome primarily through direct, sequence-specific interaction. Parsing the CEBP cistrome by individual 8-mer variants of the CEBP core motif reveals that the sequence bound most frequently by CEBPβ and CEBPα is TTGTGCAA (Figure 1E), partly due to its high occurrence in the genome (Supplementary Figure S1D). Nevertheless, this sequence accounts for only about 14% of high-confidence ChIP-exo-annotated binding sites. Together with similar ChIP-seq occupancy strengths observed as a function of CEBP 8-mers (Supplementary Figure S1E), these data indicate that no singular sequence explains the majority of CEBP binding. Interestingly, the CEBPβ-ATF4 heterodimer sequence, TGATGCAA, is the second most prevalent CEBP core motif variant, and additional hybrid motifs composed of non-CEBP bZip half sites (TGWN) joined to the CEBP half site are also present within the top-ranked sequences. The tolerance of substituting G in lieu of the canonical T at the 2nd position of the hybrid core is highly suggestive of broadened motif recognition through heterodimerization. However, we cannot formally exclude the possibility that modulation of CEBP activity in certain physiological contexts drives CEBP homodimers to lower-affinity sites. As a whole, the ChIP-exo data demonstrate conservation between human and mouse CEBP family members through interaction with a compound motif anchored by a CEBP half site.

The CEBP motif identified in primary cells and tissue differs strikingly from the optimal sequence observed for homodimers in vitro. Both early studies (63–66) and more recent systematic biochemical approaches (9,10,67) revealed that the CEBP palindromic 8-mer occurs rarely in the fact that the CEBP palindromic 8-mer occurs rarely in the human genome, it exhibits the highest fraction of genomic occupancy of any CEBP motif (Supplementary Figure S1D). This suggests a relationship between sequence optimization and probability of genomic occupancy. To test whether motif optimization is correlated with the likelihood of binding and/or transcriptional regulation, we examined the relationships between CEBPβ-binding sites, CEBP motifs, and gene transcription across multiple human cell lines (hMSCs, Helas3, HepG2, K562, IMR90, A549). Consistent with frequency measurements for shared versus unique binding sites for a TF in different cell types (26,68), and CEBPβ specifically (69), approximately 20% of CEBP sites map to either a single cell type (cell-type specific) or all cell types (cell-type independent), respectively, while the remaining 60% fall between these extremes (Figure 2A). Functional CEBPβ sites show enrichment for RNA Polymerase II (RNAPII) (69), and using gene body RNAPII occupancy as a surrogate for transcription, we observed higher transcriptional activity at genes near cell-type-independent sites compared to genes near cell-type-specific sites (Figure 2B). Moreover, distinct gene ontologies were observed, with genes near cell-type-independent sites enriched for general processes such as mRNA metabolism and translation, whereas cell-type-specific site-gene pairs associate with specialized pathways such as adipocytokine signaling and lipoprotein metabolism. Intriguingly, the genomic distribution of cell-type-independent sites is biased towards transcription start sites (TSSs), whereas cell-type-specific sites display a gene-distal distribution characteristic of the overall CEBPβ cistrome (Supplementary Figure S2A).

Motif quality has been reported to correlate with shared occupancy across cell types for some nuclear receptors (26,70), but prior studies of cell-type-dependent binding for CEBPβ focused on the role of collaborating TFs and chromatin (69). Interestingly, de novo motif analyses revealed a
depletion of C in the fifth position of the CEBP motif at cell-type-specific, but not cell-type-independent, sites (Figure 2C). This C conforms to the canonical CEBP half site, suggesting that the probability of CEBP binding occupancy is correlated with motif optimization. To further elucidate this relationship, we surveyed the utilization of the top motif variants in both classes of sites. Preservation of C at the fourth position of the core 8-mer (fifth position of the 10-mer) was strongly correlated with increased probability of binding in multiple cell types, with 90% co-occupancy of the CEBP palindrome in 4 or more cell types (Figure 2D). Conversely, cell-type-specific sites are enriched for sub-optimized motifs, harboring substitutions in the fourth and sixth positions of the core 8-mer. Consistent with the hypothesis that cell-type-independent binding sites are privileged for both high-affinity motifs and highly accessible chromatin, average CEBP-binding strength is positively correlated with co-occupancy status (Supplementary Figure S2B). These data demonstrate that motif optimization within the core 8-mer increases the probability that any given CEBP-binding site will be shared across cell types, and also suggest a relationship between optimized CEBP motifs and increased transcriptional activity. Though rare genome-wide, optimized CEBP motifs may serve as elite sequences that enable CEBP to overcome the repressive effects of chromatin to coordinate a limited program of constitutive gene expression.

**Bases directly abutting the core CEBP motif impact occupancy**

We would predict occupancy at that nearly every genomic instance of the palindromic CEBP core 8-mer if this motif constitutively recruits CEBPs, and yet most are unoccupied in hMSCs (Supplementary Figure S1D). To investigate potential distinguishing features for bound versus unbound CEBP palindromes, we profiled CEBP binding occupancy at all 3121 palindromic 8-mers (excluding unplaced contigs) in the human genome using our in vitro ChIP-exo data derived from recombinant CEBP homodimer bound to histone-free genomic DNA. While the vast majority (84%) of CEBP palindromes showed binding, a subset failed to recruit CEBP. Sequence alignments of these unbound sites revealed a pronounced difference in the base composition at positions immediately flanking the core motif (Figure 3A). In contrast, neighboring positions beyond these flanks have random sequence variation (Supplementary Figure S3A). Strikingly, the occurrence of T at the 5′ flank or A at the 3′ flank is negatively correlated with CEBP binding occupancy. Moreover, while C is also disfavored at the 5′ flank, its ability to cripple the functionality of the palindromic 8-mer is most pronounced when paired with A at the 3′ flank. Likewise, T-G dinucleotide flanks appear highly deleterious to CEBP binding (note that TTGGCGCAAA and TTGGCGCAAG are reverse-complementary 10-mer sequences). Importantly, sequence preferences at these flanking positions are implicit within the motif logos from our ChIP-exo experiments (Figure 1C, Supplementary Figure S1B). Careful inspection of these logos reveals the exclusion of T at the 5′ flank and A at the 3′ flank. However, compared to the core 8-mer, the relatively low information content encoded in these flanks de-emphasizes their importance, and fails to underscore how specific base pairings at the 5′ and 3′ flanks (T-A, C-A, T-G) can override the ability of an optimized 8-mer core sequence to recruit CEBP.

The apparent importance of the flanking bases indicates that the minimal sequence determinant for CEBP binding...
Figure 3. Bases directly flanking the core CEBP 8-mer affect occupancy. (A) Density heat map of the in vitro ChIP-exo reads for the CEBPβ homodimer at all canonical palindromic 8-mers with mappable sequence. Binding strength is ordered from top to bottom. Color charts show the base identity at the first position next to the 8-mer on the 5′ and 3′ ends. Grey boxes indicate sites without detectable ChIP-exo reads. (B) Histogram interrogating relationship between flanking bases and CEBPβ occupancy at the canonical palindromic 8-mer. Equivalent flanking pairs (5′-3′) are grouped together. ENCODE ChIP-seq peak calls are plotted across 6 cell types (left y-axis) and compared to SMiLE-seq results (right y-axis). Favorable flanks associate with occupancy in most cell types at most locations and high-frequency binding in SMiLE-seq data. Unfavorable flanks are not occupied in any cell type at most locations and are rarely bound in SMiLE-seq. (C) CEBPβ ChIP-exo reads at a ChIP-seq peak (insert) from hMSCs with 3 CEBP motifs of the form TKnnGCAA. Purple shading indicates motif locations. Binding to the primary motif (right) is indicated by co-localization with an opposite-stranded peak pair. The secondary motifs co-localize with either a weaker peak pair having too few reads to meet binding cutoffs (left) or background reads (center). Flanking bases (larger font) are indicated as favorable (red) or unfavorable (blue) based on the findings from the palindromic 8-mer. (D) Polar bar graphs indicating the frequency of each pair of bases (5′ and 3′) flanking a generic CEBP motif at primary and secondary motifs. Comparison of the frequencies for favorable, intermediate and unfavorable flanks between the secondary weakly bound versus unbound motifs are highly statistically significant (E-13 by hypergeometric distribution).
to the genome is encoded by a 10-mer sequence, corroborating earlier biochemical and structural studies that identified a 5-mer half-site (63–66). To further investigate the relationship between sequence variation at core-motif flanking positions and motif binding strength, we revisited our analysis of cell-type-dependent occupancy across all 3121 CEBP palindromic motifs, parsing by 10-mer variants (Figure 3B). Remarkably, 88% of all genomic instances of the top-6 performing 10-mers are co-occupied by CEBPβ in 5 or more cell types (red bars), and ≥ 95% of these sequences are bound in at least one cell type (sum of red and green bars). Conversely, 10-mers comprised of a palindromic 8-mer nested within unfavorable flanks are rarely occupied. These data indicate that flanking nucleotides play a critical role in CEBP motif recognition, and reveal that when annotated as a 10-mer sequence, the CEBP palindromic functions to recruit CEBPβ independently of cell type or genomic neighborhood. In contrast, 8-mer palindromic sequences with neutral flanking dinucleotide pairs (combinations of one favorable and one unfavorable flanking nucleotide at the 5′ and 3′ positions) are enriched for cell-type-specific CEBPβ binding, suggesting that while these sequences have the potential to recruit CEBPs, they are more sensitive to cell-type-specific differences in chromatin structure. Reduced affinity for these sequences could explain this behavior, which is indicated by weaker ChIP-exo signal at sites with neutral flanking bases relative to those with favorable flanks (Supplementary Figure S3B). Indeed, examination of CEBPβ SMiLE-seq data reveals a direct correlation between the progression of favorable-to-unfavorable flanks at the palindromic 8-mer and high-to-low binding frequency in vitro (Figure 3B).

These findings enhance our understanding of the optimal CEBP palindromic motif, yet an important question is whether core-motif flanking nucleotides are also important in the context of a more degenerate CEBP motif that is representative of the broader CEBP cistrome. However, the very nature of these degenerate sequences as sub-optimized binding sites presents a challenge in interpreting whether unbound genomic sequences fail to recruit CEBPβ due to chromatin effects, unfavorable flanks, or both. Importantly, the effects of chromatin can be excluded by testing how CEBP 8-mers are populated within known CEBPβ ChIP-seq peaks, which by definition reside within accessible chromatin. While ChIP-exo has the resolution to resolve multiple binding events within single ChIP-seq peaks for CEBPβ, our analysis pipeline picks the strongest peak pair with a characteristic spacing per ChIP-seq peak, and thus does not explicitly identify every instance of a bound motif. As a result, we re-interrogated our ChIP-exo data to discover additional, weaker CEBPβ-binding events within CEBPβ ChIP-seq peaks, and compared their motifs to co-localized 8-mer sequences that failed to exhibit a characteristic ChIP-exo peak pair. A total of 3686 CEBP motif candidates were mapped in the vicinity of a CEBP-bound motif, and classified into bound versus unbound sequences based on their ChIP-exo signature (Figure 3C, Supplementary Figure S3C). Within the set of candidate secondary motifs, 61% lacked appropriately spaced opposite-stranded peak pairs, indicating little or no occupancy. We then examined the frequency of dinucleotide flanks abutting the bound primary and secondary CEBP 8-mers as well as the unbound secondary 8-mers (Figure 3D). Consistent with the behavior of the flanks surrounding the palindromic 8-mer, the flanks present at primary (strong) ChIP-exo bound motifs are enriched for A-T, A-C, A-G, G-T, G-C and C-T dinucleotide flanks, whereas the unfavorable T-A, C-A and T-G flanks are essentially absent. This frequency distribution differs from the background rate for CEBP 8-mers across the human genome (Supplementary Figure S3D), such that favorable flanks occur less frequently than expected by chance. Secondary bound CEBP motifs show a preference for favorable flanks that is similar to primary sites, albeit at lower frequencies. In contrast, unbound 8-mers are enriched for unfavorable and neutral flanks. These data demonstrate that flanking bases play a role in discriminating which candidate CEBP 8-mers are bound within regions of open chromatin. Combined with the earlier analyses, they reveal that a 10-mer sequence enables discrimination of real versus decoy CEBP motifs in the genome.

### Bases directly abutting core bZip motifs affect DNA shape

Crystallography studies of CEBPα and several other bZip proteins complexed with DNA have modeled contacts to the core bases (71–75), whereas interaction with the DNA backbone may take place at the flanks (74). These observations challenge the notion that the flanks interact with CEBPs via base readout, and led us to consider whether the flanking bases could impact genomic occupancy through alteration of DNA shape. To address DNA shape in an unbiased manner, we examined the CEBP motifs residing in accessible chromatin of hMSCs yet differing in their ability to recruit CEBPβ (see Supplementary Figure S3C). Comparison of intrinsic DNA shape features revealed significant differences between bound versus unbound motifs (Figure 4A). The shape changes occurred at or near the flanking bases, consistent with an intimate association between sequence and shape, and suggesting that CEBPβ prefers to bind motifs surrounded by more positive roll, less helical twist, wider minor groove width, and less negative propeller twist.

More broadly, we sought to determine whether the DNA shape features associated with CEBPβ occupancy apply to bZip TFs in general. To examine a potential relationship between DNA shape and bZip TF occupancy, we identified weakly and strongly bound motifs from published PBMs for CREB, NFIL3 and JUND (10). Comparison of differentially bound motifs for each TF revealed significant alterations for various shape features (Figure 4B). Interestingly, the shape changes resembled those at the CEBP motif, suggesting that CREB, NFIL3 and JUND prefer to bind motifs surrounded by more positive roll, less helical twist, wider minor groove width, and less negative propeller twist. Given that DNA sequence determines shape, we examined the motifs enriched in previously published ChIP-seq datasets for CREB, NFIL3 and AP-1 (76). Similar to the CEBP motif, we found a clear exclusion of T and A in the 5′ and 3′ flanking positions, respectively (Figure 4C). Thus, the motifs for multiple bZip proteins share similar negative selection for T-A pairs at the flanks, indicating that an expanded mo-
Figure 4. Bases directly flanking core bZip motifs influence DNA shape. (A) Density heat maps of DNA shape features (roll, helical twist, minor groove width and propeller twist) at occupied and unoccupied CEBP motifs within CEBPβ ChIP-seq peaks from hMSCs. CEBPβ ChIP-exo signal sets the ordering for all heat maps. F indicates the positions flanking the core 8 bp motif. * denotes P < E–50, Wilcoxon rank sum test. (B) Average profile plots of DNA shape parameters at weakly and strongly bound motifs for CREB, NFIL3 and JUND. Differential binding was determined by protein binding microarrays (10). Core motifs and flanking positions (f) are shown. Dashed line indicates the genome-wide average for each shape feature. *P < 0.01, Wilcoxon rank sum test. (C) Motif analyses of CREB1, NFIL3 and AP-1 ChIP-seq data. Top-ranked motif is shown for each emphasizing de-enriched bases in the 5′ and 3′ positions flanking the core sequences. Negative selection of bases within the cores is not shown.

**Bases directly abutting core bZip motifs affect transcriptional activity**

To test whether a change in the flanks is sufficient to convert a functional CEBP-binding site into a crippled site, we performed ChIP for CEBPs in liver tissue isolated from C57BL/6J (B6) and 129S1/SvImJ (129) mice, and examined occupancy at sites carrying SNPs that introduce unfavorable flanks into CEBP-binding sites when comparing B6 to 129. While only two sites exist meeting the criteria for type of nucleotide substitution of interest and the absence of a neighboring CEBP-binding site, both show diminished occupancy of CEBPα and CEBPβ in 129 mice relative to B6 (Figure 5A). Consistent with these results, B6 × 129 F1 mice showed significantly skewed binding of CEBPs to the B6 alleles (Figure 5B). Because the B6 and 129 alleles re-
Figure 5. Bases directly flanking core bZip motifs regulate function. (A) CEBP ChIP in liver tissue isolated from B6 and 129 mice interrogating binding sites with and without SNPs in the bases flanking the core CEBP 8-mer. ChIP-exo tracks (bottom) show location of SNP relative to core 8-mer and opposite-stranded peak pairs. Ins1, non-specific control site. Error bars depict SEM from 5 biological replicates. *P < 0.05, Student’s t-test comparison of B6 with 129. (B) Pyrosequencing of CEBPα, CEBPβ and IgG ChIP DNA prepared from liver tissue of B6 × 129 F1 mice. Chromatograms show raw data for SNP2. Note that these data report the opposite DNA strand shown in A. Bar plot (lower left) reports results for SNPs 1 and 2 with error bars depicting SEM from 5 biological replicates. *P < 0.05, Student’s t-test comparison of CEBPα or CEBPβ with IgG. (C) Core bZip motifs were assembled into repeats of four and assayed by a luciferase reporter in HEK293T cells. Flanking bases (X-X) for the CEBP (XTTGTGCAAX), ATF4 (XTGATGCAAX), AP-1 (XTGACTCAX), CRE (XTGACGTCAAX) and PAR (XXTACGTAAX) motifs were either favorable (A-T) or unfavorable (T-A, excepting the ATF4 motif, where a T-T pair was used to selectively target the flank of the ATF4 half site) for TF occupancy. Error bars depict SEM from 3 replicates. *P < 0.01, Student’s t-test comparison of favorable with unfavorable flanks for each motif.

We examined the activity of synthetic luciferase reporters containing multimerized core motifs for distinct bZip TFs flanked by either favorable or unfavorable bases. Replacement of favorable with unfavorable flanks decreased luciferase activity across all bZip reporter constructs tested, with reductions ranging from 6-fold for the CEBP motif to ≥ 10-fold for the remaining motifs (Figure 5C). Thus, the data reveal a shared requirement across the bZIP family for favorable motif flanks that confer binding and tran-
scriptional competency to their cognate core recognition sequences.

DISCUSSION

We have used ChIP-exo to perform a genome-wide cataloging of motif utilization within the CEBP cistromes of primary human cells and mouse liver tissue. We demonstrate species-conserved sequence requirements for the recruitment of CEBP proteins to the native genome that are fundamentally different from the sequence preferences of CEBP homodimers in vitro. Pioneering in vitro studies (63–66) and more recent systematic biochemical approaches (9,10,67) report that the CEBP homodimer prefers to bind a palindromic motif formed by the fusion of two CEBP half sites (ATTGCGCAAT). Our data reveal that this motif captures <1% of the binding sites occurring in cells. On the native genome, CEBPs bind a diversity of related sequences resulting from the fusion of degenerate and canonical CEBP half sites that yields a 10-mer-consensus of the form VTKN-NGCAAB. A large majority of binding sites, 70–90% depending on threshold cutoffs, contains bound CEBP motifs. This suggests that CEBPs primarily occupy the genome through direct, sequence-specific interaction, whereas binding to motifs with atypical spacing between half sites (24) and to other DNA-bound TFs through tethering contribute minimally to the genomic recruitment of CEBPs.

It is noteworthy that roughly 40% of CEBP-binding sites contain a G at the third position of the 10-mer, creating a preferred half-site motif for the ATF, AP-1 and CREB families of bZip TFs. Evidence has been found for the heterodimerization and altered sequence specificity of CEBP-ATF complexes compared to their homodimer counterparts (24,40,47–49), yet none of these studies addresses the extent to which heterodimerization drives genomic occupancy in vivo. For example, the identification of ~1600 ATF4-CEBPβ heterodimer sites in hMSCs represents only 2–5% of the total genomic CEBPβ sites (40). This finding and the observation that CEBP occupancy of hybrid motifs represents a large fraction of the cistrome in vivo suggest that heterodimer binding with additional bZip proteins greatly exceeds that with ATF4 in hMSCs. Widespread occupancy of hybrid motifs is unprecedented and highly impactful for understanding the function of bZip TFs, and may help to explain why CEBPs populate large cistromes comprised of tens of thousands of binding sites in mammalian tissues and primary cells (25,51–53).

An analysis of bound TF sequences suggests that optimized motifs play limited biological roles in genomic recruitment of TFs. A relationship between sub-optimized motifs and cell-type-dependent binding has been documented for ERα (26,70), yet whether deviations from consensus motifs are biological drivers of differential TF occupancy is unknown, especially given the dominant effect of chromatin structure on the accessibility of DNA motifs. Intriguingly, motif sub-optimization through somatic mutation of the central CG dinucleotide of the CEBP motif has been reported in human cancers (79), suggesting an evolutionary pressure selecting against optimized CEBP motifs that mirrors the overall sparsity of these motifs in the human genome. Of interest is the context of our work, perhaps the rarity of fully optimized TF motifs in eukaryotic genomes serves to limit constitutive genomic recruitment, suppressing the potential for TFs to trigger unregulated gene expression with regard to tissue or cell type. Conversely, the majority of CEBP-bound motifs are sub-optimized and occupied in a cell-type-specific manner. This observation fits with an emerging paradigm whereby tissue-specific gene expression is mediated by composite enhancers (23,80–82) that recruit multiple TFs through sub-optimized motifs (80,81). Rather than a fortuitous event, sub-optimization may be biologically favorable to impart a dependency of TF occupancy on chromatin environment, and render enhancers readily amenable to evolutionary turnover (83–85).
ACKNOWLEDGEMENTS

We are grateful to Raymond Soccio for guidance on the experimental strategy interrogating strain-specific TF binding, and for providing liver tissue from 129S1/SvImJ and 129S1/SvImJxC57BL/6J F1 mice. We also thank Chris Krupp and Marisa Bartolomei for help with pyrosequencing and generously providing access to their sequencer. We are indebted to members of the Lazar laboratory for insightful discussions, and also thank the Functional Genomics Core of the Penn Diabetes Center (DK19525) for deep sequencing.
