Azimuthally-differential pion femtoscopy relative to the third harmonic event plane in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV

ALICE Collaboration

1. Introduction

Heavy-ion collisions at LHC energies create a hot and dense medium known as the quark–gluon plasma (QGP) [1]. The QGP fireball first expands, cools, and then freezes out into a collection of final-state hadrons. Correlations among the particles carry information about the space–time extent of the emitting source, and are imprinted on the final-state spectra due to a quantum-mechanical interference effect [2]. Commonly known as intensity or Hanbury–Brown–Twiss (HBT) interferometry, the correlation of two identical particles at small relative momentum, is an effective tool to study the space–time (“femtoscopic”) structure of the emitting source in relativistic heavy-ion collisions [3]. The initial state of a heavy-ion collision is characterized by spatial anisotropies that lead to anisotropies in pressure gradients, and consequently to azimuthal anisotropies in final particle distributions, commonly called anisotropic flow. Anisotropic flow is usually characterized by a Fourier decomposition of the particle azimuthal distribution and quantified by the flow coefficients $v_n$ and the corresponding symmetry plane angles $\Psi_n$ [4]. Elliptic flow is quantified by the second flow harmonic coefficient $v_2$, whereas triangular flow [5] is quantified by $v_3$. Due to the position–momentum correlations in particle emission [6], the particles emitted at a particular angle relative to the flow plane carry information about the source as seen from that corresponding direction; these correlations also lead to the HBT radii to be sensitive to the collective velocity fields, from which information about the dynamics of the system evolution can be extracted.

Azimuthally-differential femtoscopic measurements can be performed relative to the direction of different harmonics event planes [7,8]. The measurements of the HBT radii with respect to the first harmonic event plane (directed flow) at the AGS [9] revealed that the source was tilted relative to the beam direction [10]. The HBT radii variations relative to the second harmonic event plane angle ($\Psi_2$) provide information on the pion source elliptic eccentricity at freeze-out. The recent ALICE measurements [11] indicate that due to the strong in-plane expansion the final-state source elliptic eccentricity is more than a factor 2–3 smaller compared to the initial-state. While the HBT radii modulations relative to $\Psi_2$ are defined mostly by the source geometry, the azimuthal dependence of the HBT radii relative to the third harmonic event plane ($\Psi_3$) originate predominantly in the anisotropies of the collective velocity fields – for a triangular, but static source the radii do not exhibit any oscillations [12]. Models studies [13,14] show that the anisotropy in expansion velocity as well as the system geometrical shape can be strongly constrained by azimuthally differential femtoscopic measurements relative to...

Wave Model [16] for a quantitative characterization of the final 
source shape.

2. Data analysis

The analysis was performed over the data sample recorded in 
2011 during the second Pb-Pb running period at the LHC. 
Approximately 2 million minimum bias events, 29.2 million central 
trigger events, and 34.1 million semi-central trigger events were 
used. The minimum bias, semi-central, and central triggers used 
all require a signal in both V0 detectors [17]. The V0 detector, 
also used for the centrality determination [18], is a small angle detector of scintillator arrays covering pseudorapidity ranges \( 2.8 < \eta < 5.1 \) and \( -3.7 < \eta < -1.7 \) for a collision vertex occurring at the 
center of the ALICE detector. The results of this analysis are reported 
for collision centrality classes expressed as ranges of the fraction of 
the inelastic Pb-Pb cross section: 0–5%, 5–10%, 10–20%, 20–30%, 30–40%, and 40–50%. Events with the primary event vertex along the beam direction \( |V_z| < 8 \) cm were used in this analysis to ensure 
a uniform pseudorapidity acceptance. A detailed description of the ALICE detector can be found in [19,20]. The Time Projection 
Chamber (TPC) has full azimuthal coverage and allows charged- 
particle track reconstruction in the pseudorapidity range \( |\eta| < 0.8 \), as well as particle identification via the specific ionization energy 
loss \( dE/dx \) associated with each track. In addition to the TPC, the 
Time-Of-Flight (TOF) detector was used for identification of particles 
with transverse momentum \( p_T > 0.5 \text{ GeV}/c \).

The TPC has 18 sectors covering full azimuth with 159 pad rows 
radially placed in each sector. Tracks with at least 80 space points 
in the TPC were used in this analysis. Tracks compatible with a 
decline in flight (kink topology) were rejected. The track quality was 
determined by the \( \chi^2 \) of the Kalman filter fit to the reconstructed 
TPC clusters [21]. The \( \chi^2 \) per degree of freedom was required to 
be less than 4. For primary track selection, only trajectories passing 
within 3.2 cm from the primary vertex in the longitudinal direction 
and 2.4 cm in the transverse direction were used. Based on the 
specific ionization energy loss in the TPC gas compared with the 
corresponding Bethe–Bloch curve, and the time of flight in TOF, a probability for each track to be a pion, kaon, proton, or electron was determined. Particles for which the pion probability 
was the largest were used in this analysis. This resulted in an 
overall purity above 95%, with small contamination from electrons in 
the region where the \( dE/dx \) for the two particle types overlap. Pions were selected in the pseudorapidity range \( |\eta| < 0.8 \) and 
\( 0.15 < p_T < 1.5 \text{ GeV}/c \).

The correlation function \( C(q) \) was calculated as

\[
C(q) = \frac{A(q)}{B(q)},
\]

where \( q = p_1 - p_2 \) is the relative momentum of two pions, \( A(q) \) 
is the distribution of particle pairs from the same event, and \( B(q) \) 
is the background distribution of uncorrelated particle pairs. The 
background distribution is built by using the mixed-event tech-
nique [22] in which pairs are made out of particles from three 
different events with similar centrality (less than 2% difference), 
event-plane angle (less than 6° difference), and event vertex position 
along the beam direction (less than 4 cm difference). Both the \( A(q) \) and \( B(q) \) distributions were measured differentially with 
respect to the third harmonic event-plane angle \( \Psi_{EP,3} \). Note, that 
measurements relative to \( \Psi_{EP,3} \) will smear any contribution from 
elliptic flow as the elliptic and triangular event planes are 
uncorrelated [23]. The third harmonic event-plane angle \( \Psi_{EP,3} \) 
determined using TPC tracks. To avoid auto-correlation each event 
was split into two subevents (−0.8 < \( \eta < 0 \) and \( 0 < \eta < 0.8 \)). Pairs 
were chosen from one subevent and the third harmonic event-
plane angle \( \Psi_{EP,1} \) was estimated using the particles from the 
other subevent, and vice-versa, with the event plane resolution 
determined from the correlations between the event planes determined 
in different subevents [4]. Requiring a minimum value in the two-
track separation parameters \( \Delta \varphi = |\varphi_1 - \varphi_2| \) and \( \Delta \eta = |\eta_1 - \eta_2| \) 
reduces two-track reconstruction effects such as track splitting or 
track merging. The quantity \( \varphi^* \) is defined in this analysis as the 
azimuthal angle of the track in the laboratory frame at the radial 
position of 1.6 m inside the TPC. Splitting is the effect when one 
track is reconstructed as two tracks, and merging is the effect of 
two tracks being reconstructed as one. Also, to reduce the 
splitting effect, pairs that share more than 5% of the TPC clusters 
were removed from the analysis. It is observed that at large relative 
momentum the correlation function is a constant, and the background 
pair distribution is normalized such that this constant is equal to 
unity. The analysis was performed for different collision centralities 
in several ranges of \( k_t \); the magnitude of the pion-pair transverse 
momentum \( k_t = (p_{T1} + p_{T2})/2 \), and in bins of \( \Delta \varphi = \varphi_{\text{pair}} - \Psi_{EP,1} \), where \( \varphi_{\text{pair}} \) is the pair azimuthal angle. The 
Bertsch–Pratt [3,24] out–side–long coordinate system was used with the long 
direction pointing along the beam axis, out along the transverse pair 
momentum, and side being perpendicular to the other two. The three-
dimensional correlation function was analyzed in the Longi-
tudinally Co-Moving System (LCMS) [25], in which the total longitudinal 
momentum of the pair is zero, \( p_{T1} = -p_{T2} \).

To isolate the Bose–Einstein contribution in the correlation 
function, effects due to final-state Coulomb repulsion must be 
taken into account. For that, the Bowler–Sinyukov fitting proce-
dure [26,27] was used in which the Coulomb weight is only applied 
to the fraction of pairs (\( \lambda \)) that participate in the Bose– 
Einstein correlation. In this approach, the correlation function is 
fitted by

\[
C(q, \Delta \varphi) = N((1 - \lambda) + \lambda K(q)(1 + G(q, \Delta \varphi))),
\]

where \( N \) is the normalization factor. The function \( G(q, \Delta \varphi) \) 
describes the Bose–Einstein correlations and \( K(q) \) is the Coulomb 
part of the two-pion wave function integrated over a source func-
tion corresponding to \( G(q) \). In this analysis the Gaussian form of \( G(q, \Delta \varphi) \) [28] was used

\[
G(q, \Delta \varphi) = \exp \left[-q_{out}^2 R_{out}^2(\Delta \varphi) - q_{side}^2 R_{side}^2(\Delta \varphi) - q_{long}^2 R_{long}^2(\Delta \varphi) - 2q_{out}q_{side} R_{side}(\Delta \varphi) - 2q_{out}q_{long} R_{long}(\Delta \varphi) - 2q_{side}q_{long} R_{side}(\Delta \varphi)\right],
\]

where the parameters \( R_{out}, R_{side}, \) and \( R_{long} \) are traditionally called 
HBT radii in the out, side, and long directions. The cross-terms \( R_{side}^2, R_{long}^2, \) and \( R_{long}^2 \) describe the correlation in the out-side, side-long, and 
out-long directions, respectively.

The systematic uncertainties on the extracted radii, discussed 
below, vary in \( k_t \) and centrality. They include uncertainties related
to the tracking efficiency and track quality, momentum resolution, different values for pair cuts (Δφ* and Δη*), and correlation function fit ranges [28]. Similarly to the azimuthally inclusive analysis [29], different pair cuts were used, with the default values chosen based on a Monte Carlo study. The difference in the results from using different pair cuts rather than the default pair cuts were included in the systematic uncertainties (1–4%). For different kT and centrality ranges, different fitting ranges of correlation function were used as the width of the correlation function depends on kT and centrality range. The difference in the results from using different fit ranges are due to the contamination of electrons in the particle identification and the non-perfect Gaussian source (1–3%). We also studied the difference in the results by using positive and negative pion pairs separately as well as data obtained with two opposite magnetic field polarities of the ALICE L3 magnet. They have been analyzed separately and a small difference in the results (less than 3%) has been also accounted for in the systematic uncertainty. The total systematic uncertainties were obtained by adding in quadrature the contributions from all various sources mentioned above. The systematic uncertainty associated with the event plane determination is negligible compared to other systematic uncertainties; the procedure for the reaction plane resolution correction of the results is described in the next section.

3. Results

Fig. 1 presents the dependence of R²_{out}, R²_{side}, and R²_{long} on the pion emission angle relative to the third harmonic event plane for centrality 20–30% and different kT ranges. Note that R²_{out} and R²_{side} exhibit in-phase oscillations (for a quantitative analysis, see below). Within the uncertainties of the measurement, R²_{long} oscillations, if any, are insignificant. Oscillations of R²_{3l} and R²_{5l} radii (not shown) are found to be consistent with zero, as expected due to the source symmetry in longitudinal direction, and are not further investigated. The curves represent the fits to the data using the functions [12]:

\[ R^2_{\mu} (\Delta \phi) = R^2_{\mu,0} + 2R^2_{\mu,3} \cos(3\Delta \phi) \quad (\mu = \text{out}, \text{side}, \text{long}), \]

\[ R^2_{0s} (\Delta \phi) = R^2_{0s,0} + 2R^2_{0s,3} \sin(3\Delta \phi). \]

Fitting the radii’s azimuthal dependence with the functional forms of Eq. (4) allows us to extract the average radii and the amplitudes of oscillations. The χ² per number of degree of freedom is 0.3–18 depending on kT and centrality range. The results for the average radii \( R^2_{\text{out},0}, R^2_{\text{side},0}, \) and \( R^2_{\text{os},0} \) were found to be consistent with those reported previously in [11] in azimuthally inclusive analysis. The extracted amplitudes of oscillations have to be corrected for the finite event plane resolution. There exist several methods for such a correction [30], which produce consistent results [31] well within uncertainties of this analysis. The results shown below have been obtained with the simplest method first used by the E895 Collaboration [9], in which the amplitude of oscillation is divided by the event plane resolution. In this analysis the event plane resolution correction factor is about 0.6–0.7, depending on centrality.

Fig. 2 shows the oscillation parameters \( R^2_{\text{out},3}, R^2_{\text{side},3}, R^2_{\text{long},3}, \) and \( R^2_{\text{os},3} \) for different centrality and kT ranges. All radii oscillations exhibit weak centrality dependence, likely reflecting the weak centrality dependence of the triangular flow itself. The kT dependence is different for different radii oscillations: while the magnitudes of \( R^2_{\text{out},3} \) and \( R^2_{\text{os},3} \) are smallest for the smallest kT range, it is opposite for \( R^2_{\text{side},3} \) and, possibly for \( R^2_{\text{long},3} \), where the oscillations become stronger. The parameter \( R^2_{\text{long},3} \) is consistent with zero within the systematic uncertainties while \( R^2_{\text{os},3} \) is positive for all centralities and kT ranges except for the lowest kT range 0.2–0.3 GeV/c. Note that \( R^2_{\text{out},3} \) and \( R^2_{\text{side},3} \) are negative for
all centralities and \( k_T \) ranges. In the toy model simulations [13] such phases of radii oscillations were observed only in the so-called “flow anisotropy dominated case” (a circular source with the radial expansion velocity including the third harmonic modulation) and not for “geometry dominated” case (triangular shape source with radial expansion velocity proportional to radial distance from the center, with corners having largest expansion velocity).

Fig. 3 shows the relative amplitudes of radius oscillations \( R_{\text{out,}3}^2/R_{\text{side,}0}^2, R_{\text{side,}3}^2/R_{\text{side,}0}^2 \) and \( R_{\text{long,}3}^2/R_{\text{long,}0}^2 \). Similar to the previous analyses and theoretical calculations [14] we report all the radii oscillations relative to the side radius the least affected by the emission time duration. There exist no obvious centrality dependence. As the average radii decrease with increasing \( k_T \), the \( k_T \) dependence of relative oscillation amplitudes appear much stronger for “out” and “out-side” radii, while “side” radius relative amplitude exhibits no \( k_T \) dependence with the uncertainties. The shaded bands in Fig. 3 indicate the results of 3+1D hydrodynamical calculations [14]. These calculations assume constant shear viscosity to entropy ratio \( \eta/s = 0.08 \) and bulk viscosity that is nonzero in the hadronic phase \( \zeta/s = 0.04 \), and the initial density from a Glauber Monte Carlo model. The parameters of the model, were tuned to reproduce the measured charged particle spectra, the elliptic and triangular flow. We find that the relative amplitudes \( R_{\text{side,}3}^2/R_{\text{side,}0}^2 \) agree with these results rather well, while the relative amplitudes \( R_{\text{out,}3}^2/R_{\text{out,}0}^2 \) and \( R_{\text{side,}3}^2/R_{\text{side,}0}^2 \) agree only qualitatively. According to the 3+1D hydrodynamical calculations, the negative signs of \( R_{\text{side,}3}^2 \) and \( R_{\text{out,}3}^2 \) parameters are an indication that the initial triaxiality has been washed-out or even reversed at freeze-out due to triangular flow [14].

To investigate further on the final source shape, we compare our results to the Blast-Wave model calculations [16]. In that model, the spatial geometry of the pion source at freeze-out is parameterized by

\[
R(\phi) = R_0 \left( 1 - \sum_{n=2}^{\infty} a_n \cos(n(\phi - \Psi_n)) \right). 
\]

where \( \Psi_n \)'s denote the orientations of the \( n \)-th order symmetry planes. The amplitudes \( a_n \) and the phases \( \Psi_n \) are model parameters. The magnitude of the transverse expansion velocity is parameterized as \( v_t = \tanh \rho \), where the transverse rapidity \( \rho \) [13,16] is

\[
\rho(\vec{r}, \phi_0) = \rho_0 \bar{f} \left( 1 + \sum_{n=2}^{\infty} 2\rho_n \cos(m(\phi_0 - \Psi_n)) \right). 
\]

Here \( \bar{f} = r/R(\phi) \), and \( \phi_0(\phi) \) is the transverse boost direction assumed to be perpendicular to the surface of constant \( \bar{f} \). The results of this model presented below were obtained assuming a kinetic freeze-out temperature of 120 MeV, and maximum expansion rapidity \( \rho_0 = 0.8 \), tuned to describe single particle spectra. Fig. 4 shows the relative amplitudes of the radius oscillations \( R_{\text{out,}3}^2/R_{\text{out,}0}^2 \) and \( R_{\text{side,}3}^2/R_{\text{side,}0}^2 \) as a function of Blast-wave model third-order parameters, spatial anisotropy \( a_3 \) and transverse flow anisotropy \( \rho_3 \). Thin dashed lines represent the lines of constant relative amplitudes, with numbers next to lines indicating the relative amplitude values. Thick dashed lines show the ALICE results for \( R_{\text{out,}3}^2/R_{\text{out,}0}^2 \) and \( R_{\text{side,}3}^2/R_{\text{side,}0}^2 \) with the thickness of the lines indicating the uncertainties. The intersection of the two dashed lines corresponds to \( a_3 \) and \( \rho_3 \) parameters consistent with ALICE measurements. The ALICE data and the Blast-Wave model calculations correspond to pairs with \( k_T = 0.6 \text{ GeV}/c \) and the centrality range 5–10%. The comparison have been also performed for other centralities and the corresponding Blast-Wave model parameters have been deduced. Fig. 5 presents the final source spatial and transverse flow anisotropies for different centrality ranges from matching the ALICE data with the Blast-Wave model calculations. The contours correspond to one sigma uncertainty as derived from
the fit of the model to the data. It is observed that the final source anisotropy is close to zero, significantly smaller than the initial triangular eccentricities that are typically of the order of 0.2–0.3. The

Fig. 3. Amplitudes of the relative radii oscillations $R_{2\text{out}}^2/R_{2\text{side},0}^2$, $R_{3\text{out}}^2/R_{3\text{side},0}^2$ and $R_{2\text{side}}^2/R_{2\text{side},0}^2$ versus centrality for four $k_T$ ranges. Square brackets indicate systematic uncertainties. The shaded bands are the 3+1D hydrodynamical calculations [14] and the width of the bands represent the uncertainties in the model calculations.

Fig. 4. The relative amplitudes of the radius oscillations $R_{2\text{out}}^2/R_{2\text{side},0}^2$, $R_{3\text{out}}^2/R_{3\text{side},0}^2$ and $R_{2\text{side}}^2/R_{2\text{side},0}^2$ on the third-order anisotropies in space ($a_3$) and transverse flow ($\rho_3$) for the centrality range 5–10% and $k_T = 0.6$ GeV/c from the Blast-Wave model [16]. The thin dashed lines show the lines of a constant relative amplitude, in magenta for $R_{2\text{out}}^2/R_{2\text{side},0}^2$ and in dark yellow for $R_{2\text{side}}^2/R_{2\text{side},0}^2$. The thick lines show the corresponding ALICE results, with width of the lines representing the experimental uncertainties. (For interpretation of the colors in the figure(s), the reader is referred to the web version of this article.)

negative values of the final source anisotropy would be interpreted as that the triangular orientation at the initial-state is reversed at freeze out.

4. Summary

We have reported a measurement of two-pion azimuthally-differential femtoscopy relative to the third harmonic event plane in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV. The observed oscillations
of the HBT radii unambiguously indicate a collective expansion of the system and anisotropy in collective velocity fields at freeze-out. Clear in-phase oscillations of $R_{\text{out}}$ and $R_{\text{side}}$, with both $R_{\text{out}}^2$ and $R_{\text{side}}^2$ parameters (as defined in Eq. (4)) being negative, have been observed for all centralities and $k_T$ ranges. According to model calculations [13] the observed $R_{\text{out}}$ and $R_{\text{side}}$ in-phase oscillations are characteristics of the source with strong triangular flow and close to zero spatial anisotropy. This conclusion is further confirmed by a detailed comparison of our results with the Blast-Wave model calculations [16], from which the parameters of the source, the spatial anisotropy and modulations in the radial expansion velocity, have been derived, with spatial triangular anisotropy being more than an order of magnitude smaller than the typical initial anisotropy values. The oscillation amplitudes exhibit weak centrality dependence, and in general decrease with decreasing $k_T$ except for $R_{\text{side}}^2$ which on opposite is the largest in the smallest $k_T$ bin. The results of the 3+1D hydrodynamic calculations [14] are in a good qualitative agreement with our measurements but, quantitatively, the model predicts a stronger dependence of $R_{\text{out}}^2$ oscillations on $k_T$ than observed in the data.

Acknowledgements

We thank J. Cimerman and B. Tomaski for providing us with the results of the Blast-Model calculations [16].

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration. Russian Federal Nuclear Center (VNIIEF), Sarov, Russia
Saha Institute of Nuclear Physics, Kolkata, India
School of Physics and Astronomy, University of Birmingham, Birmingham, United Kingdom
sección Fisica, Departamento de Ciencias, Pontificia Universidad Católica del Perú, Lima, Peru
Shanghai Institute of Applied Physics, Shanghai, China
Stefan Meyer Institut für Subatomare Physik (SMI), Vienna, Austria
SUBLETECH, IMT Atlantique, Université de Nantes, CNRS-IN2P3, Nantes, France
Suranaree University of Technology, Nakhon Ratchasima, Thailand
Technische Universität Košice, Košice, Slovakia
Technische Universität München, Excellence Cluster 'Universe', Munich, Germany
The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Cracow, Poland
The University of Texas at Austin, Austin, TX, United States
Universidad Autónoma de Sinaloa, Culiacán, Mexico
Universidade de São Paulo (USP), São Paulo, Brazil
Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil
Universidade Federal do ABC, Santo André, Brazil
University College of Southeast Norway, Tonsberg, Norway
University of Cape Town, Cape Town, South Africa
University of Houston, Houston, TX, United States
University of Jyväskylä, Jyväskylä, Finland
University of Liverpool, Liverpool, United Kingdom
University of Split, Faculty of Electrical Engineering, Mechanical Engineering and Naval Architecture, Split, Croatia
University of Tennessee, Knoxville, TN, United States
University of the Witwatersrand, Johannesburg, South Africa
University of Tokyo, Tokyo, Japan
University of Tsukuba, Tsukuba, Japan
Université Clermont Auvergne, CNRS/IN2P3, LPC, Clermont-Ferrand, France
Université Lyon, Université Lyon 1, CNRS/IN2P3, IPN-Lyon, Villeurbanne, Lyon, France
Université de Strasbourg, CNRS, IPHC UMR 7178, F-67000 Strasbourg, France
Université Paris-Saclay Centre d’Études de Saclay (CEA), IRFU, Département de Physique Nucléaire (DPhN), Saclay, France
Università degli Studi di Pavia, Pavia, Italy
Università di Brescia, Brescia, Italy
V. Fock Institute for Physics, St. Petersburg State University, St. Petersburg, Russia
Variable Energy Cyclotron Centre, Kolkata, India
Warsaw University of Technology, Warsaw, Poland
Wayne State University, Detroit, MI, United States
Westfälische Wilhelms-Universität Münster, Institut für Kernphysik, Münster, Germany
Wigner Research Centre for Physics, Hungarian Academy of Sciences, Budapest, Hungary
Yale University, New Haven, CT, United States
Yonsei University, Seoul, Republic of Korea

i Deceased.
ii Dipartimento DET del Politecnico di Torino, Turin, Italy.
iii M.V. Lomonosov Moscow State University, D.V. Skobeltsyn Institute of Nuclear, Physics, Moscow, Russia.
iv Department of Applied Physics, Aligarh Muslim University, Aligarh, India.
v Institute of Theoretical Physics, University of Wroclaw, Poland.
