$^3\Lambda$H and $\bar{^3\Lambda}$H lifetime measurement in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV via two-body decay

ALICE Collaboration

1. Introduction

Hypernuclei are bound states of nucleons and hyperons and they are mainly produced by means of $(K^-, \pi^-)$, $(\pi^+, K^+)$ and $(e,e'K^+)$ reactions on stable nuclear targets [1,2]. Hypernuclei are particularly interesting because they can be used as experimental probes for the study of the hyperon-nucleon (Y–N) interaction. The knowledge of this interaction has become more relevant in recent years due to its connection to the modeling of astrophysical objects like neutron stars [3,4]. In the inner core of neutron stars, the creation of hyperons is energetically favored compared to a purely nucleonic matter composition [5]. The presence of hyperons as additional degrees of freedom leads to a considerable softening of the matter equation of state (EOS). The resulting EOS inhibits the formation of large mass neutron stars. This is incompatible with the observation of neutron stars as heavy as two solar masses [3], constituting what is referred to as the “hyperon puzzle”. Many attempts were made to solve this puzzle, e.g. by introducing three-body forces leading to an additional repulsion that can counterbalance the large gravitational pressure and allow for larger star masses. To constrain the parameter space of such models, a detailed knowledge of the Y–N interaction and of the three-body Y–N–N interaction is mandatory, including $\Lambda$, $\Sigma$ and $\Xi$ states. The lifetime of a hypernucleus depends on the strength of the Y–N interaction, and therefore a precise determination of the lifetime of hypernuclei provides information on the Y–N interaction strength [6,7].

The recent observation of hypernuclei and the determination of their lifetimes in experiments with relativistic heavy ion collisions has triggered a particular interest. All the results published so far are related to the lightest hypernucleus, the hypertriton $^3\Lambda$H, which is a bound state formed by a proton, a neutron and a $\Lambda$, and its charge conjugate the anti-hypertriton $\bar{^3\Lambda}$H. The results have been obtained at the Relativistic Heavy Ion Collider (STAR experiment) [8], at the SIS18 (HypHI Collaboration) [9] and at the Large Hadron Collider (ALICE Collaboration) [10].

The separation energy of the $\Lambda$ in this hypernucleus is only about 130 keV [11], which results in an RMS radius (average distance of the $\Lambda$ to the deuteron) of 10.6 fm [12,13]. A very low binding energy implies a small change of the wave function of the $\Lambda$ in a nucleus and hence one can expect the lifetime of the hypertriton to be very close to that of the free $\Lambda$ hyperon ($\tau_{\Lambda} = (263.2 \pm 2.0)$ ps [14]).

Early hypertriton lifetime measurements were done with imaging techniques (i.e. emulsions, bubble chambers) and the results are lower than or consistent with the value of the free $\Lambda$ lifetime [15–20]. However, most of the measurements performed with these techniques are based on very small samples of events, thus resulting in a large statistical uncertainty. The recent measurements of the lifetime of $(anti-)^3\Lambda$H produced in ultra-relativistic heavy-ion collisions or in relativistic ion fragmentation [21], even though affected by statistical and systematic uncertainties bigger than 10%, are in agreement among each other and are lower than the free $\Lambda$ lifetime [9,10,22].

However, the few existing theoretical calculations predict that the lifetime of the $^3\Lambda$H should be very close to the lifetime of free $\Lambda$. The most comprehensive $^3\Lambda$H lifetime calculation is from Rayet and Dalitz [23]; they obtained an estimate in the range from 239.3–255.5 ps. More recent calculations from Conlleton [24] and Kamada et al. [7] yield a value of 232 ps and 256 ps, respectively.
This scenario stimulated, in the last years, a new interest from both experimentalists and theoreticians for more precise measurements of the $^3\text{He}$ lifetime.

In this letter, the lifetime of the (anti-)$^3\text{He}$ measured in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV by the ALICE experiment is presented. In Section 2, the ALICE detector is briefly described. The details of the data sample, analysis technique and systematic uncertainties are presented in Section 3, where also a new analysis approach to crosscheck the results is introduced in the subsection 3.1. Finally the result is compared with previous measurements and with theoretical predictions in Section 4.

2. The ALICE apparatus

A detailed description of the ALICE apparatus and data acquisition framework can be found in [25,26]. The main detectors used in this analysis are the V0 detector, the Inner Tracking System (ITS) and the Time Projection Chamber (TPC), which are located inside a solenoid creating a magnetic field of 0.5 T. The V0 detector [27] consists of two arrays of scintillator counters (V0A and V0C), placed around the beam-pipe on both sides of the interaction region. They cover the pseudorapidity ranges $2.8 < \eta < 5.1$ and $-3.7 < \eta < -1.7$, respectively. The V0 detector is used to define the Minimum Bias (MB) trigger, which is generated by a coincidence signal in the V0A and in the V0C, and to determine the centrality of the collisions [28]. The ITS [29] is the closest detector to the interaction point within ALICE. It is composed of six layers of silicon detectors, with radii between 39 and 43 cm from the interaction point. The six layers use three different technologies: silicon pixel detector (SPD), silicon drift detector (SDD) and silicon strip detector (SSD). The ITS has full azimuthal coverage $0 < \varphi < 2\pi$ and covers the pseudorapidity range $|\eta| < 0.9$. The TPC [30] is a gaseous detector, mainly used for tracking and for particle identification (PID) via the specific energy loss ($dE/dx$), with a total sensitive volume of 90 m$^3$ filled with a mixture of 88% Ar and 12% CO$_2$. The reconstructed clusters in TPC and ITS are the starting point of the track finder algorithm, which adopts the Kalman filter technique [31]. These tracks are used to determine the primary collision vertex with a precision better than 50 µm in the plane transverse to the colliding beams [26].

3. Data sample and analysis technique

In this letter, the lifetime of the (anti-)hypertriton is determined by exploiting the 2-body mesonic decay channel with charged pions, namely $^3\text{He} \rightarrow \pi^- + \text{He}$ and $^3\text{He} \rightarrow \pi^- + \text{He}$. Both $^3\text{H}$ and $^3\text{He}$ candidates are used for this measurement.

The analysis is performed using the data sample of Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV collected by the ALICE experiment at the end of 2015. To ensure a uniform acceptance and reconstruction efficiency in the pseudorapidity region $|\eta| < 0.9$, only those events are selected whose reconstructed primary vertex was within ±10 cm from the nominal position of the interaction point along the beam axis. The analyzed sample contains approximately 90 million events in the centrality interval 0-90%.

The $^3\text{H}$ and $^3\text{He}$ identification is based on the topology of their weak decays and on the reconstruction of the tracks of their decay products, referred to as daughter particles. The weakly decaying hypernuclei are reconstructed using the algorithm which was previously used for the K$^0_S$ and $\Lambda$ production analyses [32] and which is typically adopted for a 2-body weak decay topology. At first, the algorithm uses the TPC and ITS clusters to reconstruct the daughter tracks and then combines them in order to obtain a V-shaped decay vertex. More details on this algorithm can be found in [26,33].

The daughter tracks are selected in the pseudorapidity region $|\eta| < 0.9$ and are required to have at least 70 clusters out of 159 in the TPC, in order to guarantee a resolution $\sigma$ better than 5% on track momentum and of about 6% for the $dE/dx$ [26]. Moreover, the $\chi^2$ per TPC cluster is required to be less than 5 and tracks with kink topologies are rejected. The particle identification (PID) of the daughters ($^3\text{He}$, $^3\text{He}$, $\pi^-$) is performed following the method described in [33], which is used in many analyses of the ALICE Collaboration. It is based on the difference between the measured and the expected $dE/dx$ for a selected particle species normalized to the energy loss resolution in the detector, $\sigma$, for short, and is referred to as the $n_3$ method in this letter. In particular, an $|n_3| \leq 3$ is required, in a track-by-track approach, with respect to the expected $\pi$ and $^3\text{He}$ specific energy loss in the TPC. The pions can be identified up to a momentum of about 1.2 GeV/c, beyond which there is considerable contamination from kaons and protons. The $^3\text{He}$, having a charge of $z = 2e$, can be identified cleanly up to 7 GeV/c. The $^3\text{He}$ is also produced in the detector material due to spallation. These are produced at low transverse momenta, as reported by the ALICE experiment [34]. As a consequence the $^3\text{He}$ candidate is required to have a transverse momentum ($p_T$) greater than 1.8 GeV/c, where the spallation processes are negligible.

The $^3\text{H}$ and $^3\text{He}$ candidates are selected by applying topological and kinematic selection criteria on the decay products. The distance of closest approach (DCA) between the two daughter tracks and the DCA of $\pi^-$ tracks from the primary vertex are required to be lower than 0.7 cm and larger than 0.1 cm respectively. The candidates are selected whose cosine of the angle between the total momentum of the daughter tracks at the secondary vertex and the vector connecting the primary and secondary vertex (pointing angle) is larger than 0.995. Two additional selections on the $^3\text{H}$ and $^3\text{He}$ rapidity ($|\eta| < 0.8$) and transverse momentum ($2 < p_T < 9$ GeV/c) are applied. All the selection criteria previously described have been studied with a dedicated Monte Carlo production, in order to improve the background rejection, and are summarized in Table 1.

The sample of $^3\text{H}$ and $^3\text{He}$ candidates is divided in four $c t$ = MLC/p intervals for the lifetime determination, where $c$ is the speed of light, $t$ is the proper time of the candidate, $M$ is the mass of the candidate, $l$ is the decay distance and $p$ is the reconstructed momentum. The mass $M$ of the hypertriton is obtained from the measured values of mass of $p$, $n$ and $\Lambda$ [14] and of the binding energy [11], and has been fixed at $M = 2.99116 \pm 0.00005$ GeV/c$^2$. The four $ct$ intervals are $4 \leq ct < 7$ cm, $7 \leq ct < 10$ cm, $10 \leq ct < 13$ cm, and $13 \leq ct < 16$ cm.
15 cm and 15 ≤ ct < 28 cm. The corresponding invariant mass distributions are shown in Fig. 1 and are fitted, in each ct interval, with a function which is the sum of a Gaussian, used to interpolate the signal, and a second order polynomial, used to describe the background. The fit is performed using the maximum-likelihood estimate and the fit function is represented as a solid blue line.

From the fit, the mean values μ and the widths σ of each distribution are extracted. In particular, the signal width is in the range 1.7–2.1 MeV/c², depending on the ct interval, and is driven by the detector resolution. The raw yield of the signal is defined as the integral of the Gaussian function in a ± 3σ region around the mean value above the background. The significance of the signal in the four ct intervals varies in the range 3.1–4.9.

The yield is corrected in each ct bin for the detector acceptance, the reconstruction efficiency and the absorption of the 3He (Λ) in the detector material. The efficiency×acceptance is determined with a dedicated Monte Carlo simulation, where the 3He and Λ are injected on top of a HIJING event [35] and are allowed to decay into charged two-body and three-body final states. The simulated particles are propagated through the ALICE detectors using the GEANT3 transport code [36] and then reconstructed following the same procedure as adopted for the data.

The aforementioned transport code does not properly describe the interactions of the (anti-)hyper-nuclei with the material of the apparatus. Thus, a correction factor for the absorption of 3He (Λ) and 3He (Λ) is estimated, based on the p (p) absorption probability measured in the ALICE detector [37]. The usage of this experimental measurement offers the advantage of taking automatically into account the cross section and the effective material of the detector crossed by a charged particle. The same absorption probability for protons and neutrons has been assumed and the 3He (Λ) has been considered as a state of three independent p (p) as verified in [10]. The absorption probability, computed as the third power of that of one proton, goes from 11% at low pT to 6% at high pT for 3He while it is constant at 6% for 3He. The evaluation of the 3He (Λ) absorption cross-section is increased by 50% with respect to the one of the 3He (Λ), as described in the ALICE measurement in Pb-Pb collisions at √sNN = 2.76 TeV [10]. This leads to an absorption probability between 16% and 9% for 3He as a function of pT while it is constant at 9% for 3He. The correction factor to be applied is:

\[ k = k_{\text{abs}}^{3\text{He}} + (1 - k_{\text{abs}}^{3\text{He}})k_{\text{abs}}^{3\text{He}} \]

where \(k_{\text{abs}}^{3\text{He}}\) is the probability that the 3He is absorbed between the primary and the secondary vertex while \(k_{\text{abs}}^{3\text{He}}\) is
the probability that the daughter $^3$He is absorbed between the secondary vertex and the TPC inner wall. For each ct interval, the efficiency $\times$ acceptance has been calculated using the absorption corrected numbers of reconstructed $^3$H and $^3$He. Fig. 2 shows the efficiency $\times$ acceptance (black marker) which is used for the lifetime determination and is obtained by combining $^3$H and $^3$He after the absorption correction is applied. This distribution is also shown separately for $^3$H and $^3$He and the difference is due to the absorption correction which is bigger for the anti-matter.

The main sources of systematic uncertainties on each ct bin used for the lifetime evaluation are the absorption correction, the single track efficiency and the uncertainty on the detector material budget. The systematic uncertainty on the absorption correction is mainly due to the assumption used for the $^3$H ($^3$He) cross-section. This uncertainty is evaluated by varying this assumption between a lower and an upper limit. The first one is obtained by setting the $^3$H ($^3$He) cross-section equal to the $^3$He ($^3$He) absorption cross-section and the second one as twice the $^3$He ($^3$He) absorption cross-section. This leads to an uncertainty of 5.2% for each ct interval, as reported in Table 2.

The second source of systematic uncertainty is related to the material budget description in the simulation. An uncertainty on the knowledge of the ALICE detector material budget of 4.5% was determined in a previous study [26]. The systematic uncertainty is estimated using two dedicated Monte Carlo productions, varying the material budget accordingly, and amounts to 1% for the yields in all ct intervals.

The systematic uncertainty due to the single-track efficiency and the different choices of the track quality selections has been investigated [40] and amounts to 4%. For the analysis of the two-body decay of $^3$H an uncertainty of 8% is assumed in all ct intervals. The summary of the systematic uncertainties is reported in Table 2, where the total uncertainty is obtained as sum in quadrature of each contribution of the individual sources.

The corrected $dn/d(ct)$ spectrum is shown in Fig. 3 where the blue markers are the corrected yield with their statistical uncertainty, while the box represents the systematic uncertainty.

The lifetime is determined with an exponential fit (red line) and the slope results in a proper decay length of $ct = 7.25^{+1.02}_{-1.12}$ (stat.) $\pm 0.51$ (syst.) cm, corresponding to a lifetime $\tau = 242^{+24}_{-38}$ (stat.) $\pm 17$ (syst.) ps. The systematic uncertainty for the lifetime value is determined by assuming the systematic uncertainties in each ct interval as uncorrelated.

#### 3.1. Unbinned fit method for lifetime extraction

In order to enforce the result described in Sec. 3, an additional analysis on the same data sample has been carried out that relies on a two-dimensional (invariant mass vs. ct) unbinned fit approach. The method can be summarized in three steps: i) fit to the ct-integrated invariant mass distribution; ii) tune the function used to describe the combinatorial background; iii) fit to the ct distribution with a function which is the sum of three exponentials, one to describe the signal and two to describe the background.

The first step is performed with a function that is the sum of a Gaussian, for the signal, and a second order polynomial, for the background. The mean value $\mu$ and the $\sigma$ are $2.9913 \pm 0.0004$ GeV/$c^2$ and $0.0020 \pm 0.0005$ GeV/$c^2$ respectively and are used to define the boundaries of the signal region and the sidebands, which correspond to the intervals $\mu \pm 3\sigma$ and $\pm 3\sigma$ to $\pm 9\sigma$ with respect to the mean value, respectively.

The second step consists in fitting the ct distribution of the background in the sidebands using a function that is the sum of two exponentials. The fit is performed simultaneously in two sideband regions with the RooFit package [41]. The result is then used as background parameterization for the fit in the signal region.

The $(^3\Lambda + ^3\Sigma)$ lifetime measurement is obtained by performing the unbinned fit to the ct distribution in the signal region. The total probability density function used for the fit is the sum of the two exponentials (background) and the exponential adopted to reproduce the signal. Since the ct distribution is unbinned, the efficiency $\times$ acceptance correction, evaluated as described in Sec. 3, is parametrized with a polynomial plus an exponential and it is
used to scale the signal function. The observed signal distribution is described as the product of the function used for the signal and the efficiency parametrization. Thus, the lifetime is obtained with the unbinned maximum-likelihood estimate (MLE) fit to the $ct$ distribution, performed in the signal region, leading to a value of $\tau = 240^{+39}_{-31} \text{(stat.)} \pm 18 \text{ (syst.)} \text{ ps}$ as reported in Fig. 4. The statistical uncertainty of the measurement is assessed by providing the interval of the estimated $\tau$ [42], at a confidence level of 68%, which is represented by the red dashed lines, based on the log-likelihood ratio ($\log(\lambda(t))$, shown as a blue line. The result corresponds to a proper decay length $c\tau = 7.20^{+1.20}_{-0.93} \text{(stat.)} \pm 0.54 \text{ (syst.)} \text{ cm}$. The sources of systematic uncertainties are the same as described in Sec. 3 (Table 2) and contribute to a total systematic uncertainty of 9.5% on the estimated lifetime.

The value obtained with this approach is in good agreement within 1$\sigma$ with the lifetime estimation obtained with the method described in Sec. 3, which we consider as the final value for the $^3_H \Lambda$ lifetime. Additional figures and details for the unbinned fit method are presented in [43].

4. Discussion and conclusions

Thanks to the large data sample of heavy-ion collisions at $\sqrt{s_{NN}} = 5.02$ TeV provided by the LHC and to the excellent tracking and particle identification performance of the ALICE apparatus we have determined a precise value for the $^3_H \Lambda$ lifetime. The measured $\tau = 242^{+34}_{-28} \text{(stat.)} \pm 17 \text{ (syst.)} \text{ ps}$ is shown as a full red diamond in Fig. 5 together with other experimental results and theoretical estimates.

Early experiments [15–20] were performed with visualizing techniques, namely photographic emulsion and $^3$He filled bubble chambers, where the tracks formed due to passage of charged particles were recorded visually. Most of the results obtained using these techniques had large uncertainties due to the limited size of the data sample at disposal. Furthermore, these measurements prevented a definite conclusion on the agreement with the theoretical predictions, which foresee a lifetime close to the value of the free $\Lambda$ hyperon. It is worthwhile to note that the small binding energy of the hypertriton makes the $\Lambda$ spend most of the time far from the deuteron core thereby not affecting the lifetime due to $Y$-N interaction.

The recent determination of the lifetime $\tau$ of (anti-)$^3_H \Lambda$ of $182^{+89}_{-45} \text{(stat.)} \pm 27 \text{ (syst.)} \text{ ps}$, measured for the first time in Au–Au collisions via two-body decay by the STAR experiment at RHIC [8], revived the interest for a more precise determination of the lifetime. The HyperH Collaboration at GSI reported a value of $\tau = 183^{+32}_{-24} \text{(stat.)} \pm 37 \text{ (syst.)} \text{ ps}$ [9], which was obtained by studying the projectile fragmentation of $^6$Li at 2 AGeV on a carbon target. Very recently, the ALICE experiment at the LHC measured a lifetime value $\tau = 181^{+38}_{-28} \text{(stat.)} \pm 33 \text{ (syst.)} \text{ ps}$ [10] using the data from Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV and the invariant mass analysis of the two-body decay channel. The average value of all results available up to 2016 was $\tau = 215^{+18}_{-16} \text{ ps}$ [10], much lower than the theoretical estimates, motivating the need for a measurement with improved precision. The STAR Collaboration performed a new analysis [22] combining the two-body and the three-body decay channels using the data sample of the RHIC beam energy scan, resulting in an even lower value of $\tau = 142^{+24}_{-21} \text{(stat.)} \pm 29 \text{ (syst.)} \text{ ps}$. The ALICE Collaboration exploited the data collected in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV to carry out a new analysis of the two-body decay channel, which is reported in this letter. These two most recent values are reported in Fig. 5. The new measurement by STAR yields a very low value as compared to the lifetime of the free $\Lambda$, while the result presented in this paper is in agreement with the theoretical predictions and it is characterized by an improved precision with respect to previous experiments. This value is also in agreement with the previous ALICE result [10] obtained by analyzing the data sample of Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV.

Besides the experimental results, the theoretical predictions for the $^3\Lambda$ lifetime are reported in Fig. 5 for comparison with the data. The calculation performed by Dalitz and Rayet [23], represented with a dot-long dashed cyan line, took into account the phase space factors and the Pauli principle, including also corrections to account for final state pion scattering and the non-mesonic weak decay channel. More recently, a prediction for the $^3\Lambda$ lifetime quite close to the one of the free $\Lambda$ hyperon was published by Congleton [24] (dashed green line in Fig. 5), obtained using updated values for N–N and Y–N potentials. The prediction by Kamada et al. [27] (dotted-dashed blue line) was performed with a rigorous determination of the hypernucleus wave function and of the three nucleons scattering states, thus finding a value of 256 ps, which is the closest to the free $\Lambda$ lifetime value. Recently, Garcia and Gal performed a calculation [44] using the wave function generated by solving three-body Faddeev equations and adding the final-state interactions of the pions. Their prediction of 213 ps is shown as a dotted purple line.

A statistical combination of all the experimental results, including the most recent values determined by the STAR and ALICE experiment, leads to a world average of $\tau = 206^{+13}_{-12} \text{ ps}$ for the $^3\Lambda$ lifetime and is represented with an orange band in Fig. 5. The method used for this evaluation is the same as described in [10]. Furthermore world averages were calculated grouping the measurements on the basis of the experimental techniques, obtaining $\tau_{\text{visual}} = 224^{+23}_{-20} \text{ ps}$ and $\tau_{\text{חל}} = 189^{+20}_{-19} \text{ ps}$ for the visualizing techniques and the heavy-ion experiments, respectively. These values are consistent and in agreement, also with the world average, and this suggests that the results are not affected by the technique used for the measurement.

Despite the addition of two recent high precision measurements of the $^3\Lambda$ lifetime, one well below and the other closer to the theoretical predictions, the situation has hardly changed with the current world average, now more than 3 $\sigma$ below the lifetime of the free $\Lambda$ hyperon. In the future a very large data sample will be collected with heavy-ion collisions during LHC Run 3 (2021–2023) and Run 4 (2027–2029) [45]. At the end of Run 4, ALICE expects to reduce the statistical uncertainty on the lifetime down to 1% and significantly improve the systematic uncertainty,
which at present is 9.5%. Furthermore, it would be beneficial in view of a more solid comparison with the theoretical predictions, to have new measurements performed at lower energies at RHIC and SIS and by using different experimental techniques at the J-PARC and MAMI facilities. A measurement of the lifetime to a precision of a few percent will guide and constrain the theoretical input leading to a more precise determination of the Y-N interaction, eventually contributing to solving the hyperon puzzle.

Acknowledgements

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration. ALICE Collaboration

92 Nuclear Physics Group, STFC Daresbury Laboratory, Warrington, United Kingdom
93 Nuclear Physics Institute of the Czech Academy of Sciences, Rež a Praha, Czech Republic
94 Oak Ridge National Laboratory, Oak Ridge, TN, United States
95 Ohio State University, Columbus, OH, United States
96 Petersburg Nuclear Physics Institute, Gatchina, Russia
97 Physics department, Faculty of science, University of Zagreb, Zagreb, Croatia
98 Physics Department, Panjab University, Chandigarh, India
99 Physics Department, University of Jammu, Jammu, India
100 Physics Department, University of Rajasthan, Jaipur, India
101 Physikalisches Institut, Eberhard-Karls-Universität Tübingen, Tübingen, Germany
102 Physikalisches Institut, Ruprecht-Karls-Universität Heidelberg, Heidelberg, Germany
103 Physik Department, Technische Universität München, Munich, Germany
104 Politecnico di Torino, Turin, Italy
105 Research Division and Extreme Matter Institute EMMI, CSI Helmholtzzentrum für Schwerionenforschung GmbH, Darmstadt, Germany
106 Rudjer Bošković Institute, Zagreb, Croatia
107 Russian Federal Nuclear Center (VNIIEF), Sarov, Russia
108 Saha Institute of Nuclear Physics, Homi Bhabha National Institute, Kolkata, India
109 School of Physics and Astronomy, University of Birmingham, Birmingham, United Kingdom
110 Universidad de la Habana, Pontificia Universidad Católica del Perú, Lima, Peru
111 Shanghai Institute of Applied Physics, Shanghai, China
112 q.t. Petersburg State University, St. Petersburg, Russia
113 Stefan Meyer Institut für Subatomare Physik (SMI), Vienna, Austria
114 SUBATECH, IMT Atlantique, Université de Nantes, CNRS-IN2P3, Nantes, France
115 Suranaree University of Technology, Nakhon Ratchasima, Thailand
116 Technical University of Košice, Košice, Slovakia
117 Technische Universität München, Excellence Cluster 'Universe', Munich, Germany
118 The Henryk Niewodniczanski Institute of Nuclear Physics, Polish Academy of Sciences, Cracow, Poland
119 The University of Texas at Austin, Austin, TX, United States
120 Universidad Autónoma de Sinaloa, Culiacán, Mexico
121 Universidade de São Paulo (USP), São Paulo, Brazil
122 Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil
123 Universidade Federal do ABC, Santo André, Brazil
124 University of Cape Town, Cape Town, South Africa
125 University of Houston, Houston, TX, United States
126 University of Jyväskylä, Jyväskylä, Finland
127 University of Liverpool, Liverpool, United Kingdom
128 University of Science and Technology, Beijing, China
129 University of South-Eastern Norway, Oslo, Norway
130 University of Tennessee, Knoxville, TN, United States
131 University of the Witwatersrand, Johannesburg, South Africa
132 University of Tokyo, Tokyo, Japan
133 University of Tsukuba, Tsukuba, Japan
134 Université Clermont Auvergne, CNRS/IN2P3, LPC, Clermont-Ferrand, France
135 Université de Lyon, Université Lyon 1, CNRS/IN2P3, IPN-Lyon, Villeurbanne, Lyon, France
136 Université de Strasbourg, CNRS, IPHC UMR 7178, F-67000 Strasbourg, France
137 Université Paris-Saclay Centre d’Études de Saclay (CEA), IRFU, Département de Physique Nucléaire (DPhN), Saclay, France
138 Università degli Studi di Firenze, Firenze, Italy
139 Università degli Studi di Parma, Parma, Italy
140 Università di Brescia, Brescia, Italy
141 Variable Energy Cyclotron Centre, Homi Bhabha National Institute, Kolkata, India
142 Warsaw University of Technology, Warsaw, Poland
143 Wayne State University, Detroit, MI, United States
144 Westfälische Wilhelms-Universität Münster, Institut für Kernphysik, Münster, Germany
145 Wigner Research Centre for Physics, Hungarian Academy of Sciences, Budapest, Hungary
146 Yale University, New Haven, CT, United States
147 Yonsei University, Seoul, Republic of Korea

1 deceased.

II Dipartimento DET del Politecnico di Torino, Turin, Italy.

M.V. Lomonosov Moscow State University, D.V. Skobeltsyn Institute of Nuclear Physics, Moscow, Russia.

Department of Applied Physics, Aligarh Muslim University, Aligarh, India.

Institute of Theoretical Physics, University of Wroclaw, Poland.
