ABSTRACT
We study the linear and nonlinear thermovoltage of a quantum dot with effective attractive electron–electron interaction and weak, energy-dependent tunnel coupling to electronic contacts. Remarkably, we find that the thermovoltage shows signatures of repulsive interaction, which can be rationalized. These thermovoltage characteristics are robust against large potential and temperature differences well into the nonlinear regime, which we expect can be demonstrated in current state-of-the-art experiments. Furthermore, under nonlinear operation, we find extended regions of large power production and efficiency.

Recently, different types of devices with an effectively attractive electron–electron interaction have been experimentally investigated and quantum dot structures with attractive onsite-interaction have also been realized. In these quantum dots, signatures of pair tunneling induced by the attractive onsite interaction could be identified in transport properties.

In the present letter, we predict surprising features in the thermovoltage of such quantum dots. We show that the linear-response thermovoltage—the Seebeck coefficient—shows signatures at quantum-dot level positions that are characteristic of Coulomb oscillations due to repulsive onsite interaction. We rationalize this fact and show that it can be exploited in an analysis of how these features are modified under various realistic experimental conditions. The discussed effects are highly relevant for the characterization of attractive systems, which has only recently started.

Simultaneously, there has been significant progress in investigating linear and nonlinear response thermoelectrics in quantum dot devices (see Refs. 8–20 and references therein). These are of interest for on-chip energy harvesting, and their Seebeck coefficient is a key parameter to characterize them. Our analysis instead reveals the thermoelectric properties of systems with strong attractive electron–electron interaction. We also explicitly address energy-dependent tunnel couplings between the dot and the environment as energy filters in addition to the quantum-dot levels. Efficient nanoscale thermoelectrics, in particular three-terminal energy harvesters, crucially rely on this energy-dependent coupling. In this Letter, we characterize the performance of such quantum dots with attractive interaction as steady-state heat engines and find extended regions of large power production at efficiencies on the order of the Curzon–Ahlborn bound interrupted only by a characteristic sharp dip.

H = ħN − |U|N_f N_j, (1)

with ħ being the single-level energy, N = N_f + N_j, the local particle-number operator with spin-resolved components N_f and N_j, and
[|U| = -U] the interaction strength. The quantum dot is tunnel-coupled to two electronic reservoirs, a = L, R, with electrochemical potentials $\mu_a = \mu - V$ and $\mu_R = \mu$ and temperatures $T_L = T + \Delta T$ and $T_R = T$. We assume the experimentally relevant case of weak tunnel rates $\Gamma_s(E) \ll T$, implying that pair tunneling is enabled by thermal excitations.\textsuperscript{16,26,27} We allow these rates to strongly depend on the energy of the tunneling process. We set $k_B = h = |e| = 1$.

We analyze the full thermoelectric response of the quantum dot using expressions obtained from a recently established, general fermionic duality.\textsuperscript{16,19,25,28} This purely dissipative symmetry, applied to a weak-coupling master-equation description, maps the transport dynamics of fermionic open nonequilibrium systems to those of dual systems with sign-inverted local energies, description, and energy dependencies of the tunnel couplings, replacing $[\tilde{E}, -|U|, \mu_L, \Gamma_s(E) \rightarrow [-\tilde{E}, |U|, -\mu_R, \Gamma_s(-E)].$ In the present case, the remarkable duality enables us to predict nonequilibrium effects in the thermoelectric response of the attractive dot of interest by relating them to the properties of the quantum dot with equilibrium parameters and attractive interaction as well as to its dual model with repulsive interaction.\textsuperscript{19}

The key quantities in this analysis are the equilibrium dot occupation for attractive interaction,

$$n(e, -|U|) = \langle N \rangle = \frac{2f(e)}{1 + f(e) - f(e - |U|)},$$

with $e = \tilde{E} - \mu$ and $f(x) = \frac{\exp(x/T) + 1}{\exp(x/T) - 1}$ the Fermi function, and most importantly, the dual occupation,

$$n_d = n(-e, |U|) = \frac{2[1 - f(e)]}{1 - f(e) + f(-e - |U|)},$$

Figure 1(c) shows both $n$ and $n_d$ as functions of $e$.

We start with the linear response of the thermovoltage, for small $V$ and $\Delta T$, and the linear Seebeck coefficient $S = V/\Delta T$ \textsuperscript{1,9} at vanishing charge current $i = 0$ [see Eq. (10)] across the dot and first consider energy-independent tunnel couplings $\Gamma_s(E) \rightarrow \Gamma_s$. The explicit formula for $S$ has a remarkably simple form\textsuperscript{16} in terms of the dual dot occupation (3),

$$S \times T = e - |U|(2 - n_d)/2.$$

The consequences of the attractive interaction are shown in Fig. 1(b). On the one hand, we find a linear $e$-dependence $S \times T \approx e - |U|/2$ around the zero-crossing at $e = |U|/2$. This is intuitively expected in analogy to the well-known case of repulsive quantum dots,\textsuperscript{16,30–32} as reflected by $n(e)$ in Fig. 1(c), the attractive dot effectively acts as a single resonance at $e = |U|/2$. On the other hand, we find $S \times T \rightarrow e - |U|$ for $e < 0$ and $S \times T \rightarrow e$ for $e > |U|$. Here, the attractive interaction does not anymore favor thermally excited pair transitions over single-electron transitions. The resulting crossovers between all three identified regimes lead to surprising kinks in the Seebeck coefficient $S(e)$ [blue line in Fig. 1(b)]. These kinks are even better visible in its derivative\textsuperscript{2} [green, dashed line in Fig. 1(b)], measurable using lock-in techniques,

$$T \times \frac{\partial S}{\partial e} = 1 + \frac{n_d^2}{2T}.$$
implying that an asymmetry $\Lambda > 0$ favors emission from a doubly occupied dot at addition energy $e - |U|$ and $\Lambda < 0$ favors absorption into an empty dot at energy $e$. This offset of $S(e)$ in Eq. (8) involves a zero crossing $\delta_0$ shifted away from $|U|/2$ by $\Delta \delta_0 \rightarrow |U|/2 \times \Lambda$, predicting a pronounced effect for strong attractive interaction. The limit $\Delta \delta_0 \rightarrow \pm |U|/2$ for $\Lambda \rightarrow \pm 1$ reflects that transport is reduced to a single resonance at $e = 0$ or $e = |U|$, annulling all two-electron features.

Next, Fig. 2(c) demonstrates how the peaks in $\partial S/\partial e$, and hence the kinks in $S$ visible in Fig. 1(b), change with energy-dependent couplings. For $\Lambda > 0$, the peak in $\partial S/\partial e$ around $e = 0$ shrinks with larger $|\Lambda|$, whereas the peak in $\partial S/\partial e$ around $e = |U|$ grows. At the same time, the latter also moves substantially further away from resonance—we refer to this shift from resonance as $\Delta \delta_0$. For $\Lambda < 0$, the behavior is opposite with respect to the two peaks. In the single-resonance limit $|\Lambda| \rightarrow 1$, the slope $\partial S/\partial e \times T \rightarrow 1$ becomes constant and both peaks disappear, as expected.

The change in the relative peak height follows from the offset of $S$ within $0 < e < |U|$ described in Eq. (8). For example, $\Lambda > 0$, the shift to smaller $S$ in this $e$-interval causes the step of $S(e)$ around $e = 0$ to be smaller than around $e = |U|$, see Fig. 2(b). This leads to a smaller relative peak height in $\partial S/\partial e$.

The growing shift $\Delta \delta_0$ of the higher peak for increasing $|\Lambda|$ stems from the fact that the coupling asymmetry $\Lambda$ not only affects $S$ for $0 < e < |U|$ and large $|U|/T$ as in Eq. (8) but, in general, also influences where the zero between the single-particle, linear limits $(S(e) \sim e$ and $S(e) \sim |U|)$ and the two-particle limit $(S(e) \sim e - |U|/2)$ takes place [see Eq. (6)]. For both small $|\Lambda|$ and large $|\Lambda| \approx 1$, a useful analytical expression is [including the spinegneracy shift $\Theta(2)$]

$$\Delta \delta_0 \approx T \times \text{sgn}(\Lambda) \times \ln \left[ 2/(1 - |\Lambda|) \right].$$

For example, $\Lambda = 0.8$ yields $\Delta \delta_0 \approx 3.37 T \Theta(2)$, which substantially deviates from the wideband limit result, where the shift away from resonance is given by $\Theta(2)$. In this case, $\Gamma_U$ is large enough compared to $\Gamma_L$, such that even for a considerable interval with $e > 0$ and $e - |U| > 0$, the physics of pair tunneling prevails. Namely, a thermally excited electron entering the dot at energy $e$ causes transport of further electrons at energy $e - |U|$ before the dot is emptied again.

Next, we demonstrate how the Seebeck coefficient gets modified in the nonlinear regime due to large $\Delta T$ and $V$. This is also relevant below where we discuss the performance of the quantum dot as a thermoelectric device. The nonlinear thermovoltage $S_{nl} = V_{nl}/\Delta T$ quantifies the voltage $V = \mu - \mu_L$ required to suppress a charge current $I$ induced by a large temperature difference $\Delta T = T_L - T$ across the junction.

We have previously shown, the nonlinear current to take the compact form,

$$I = \frac{\gamma R}{T} n_l - n_R,$$

in the wideband limit $(\Gamma_{UL} = \Gamma_{LR} = \Gamma)$. This depends on the difference between equilibrium occupations $n_R = n_l = n$ and on the energy-level dependent charge relaxation rates $\gamma R/l = \Gamma R/l(1 + f_R(e - |U|))/|U| > 0$. Both the occupations and relaxation rates can be understood as if the dot was coupled only to the right or left lead; the symbols $f_R(e) = f(e)$ and $f_L(e) = f(e)$ denote the corresponding Fermi functions. Setting $I = 0$ while keeping the potential $\mu_L = \mu$ and temperature $T_R = T$ fixed, Eq. (10) yields the helpful analytical result for the thermovoltage,

$$S_{nl} = \frac{x}{e} = \frac{T + \Delta T}{\Delta T} \ln \left[ \frac{1 - n_R + \sqrt{(1 - n_R)^2 + \exp \frac{|U|\Delta T}{(T + \Delta T)}) n_R}} 2 - n_R \right],$$

again expressed in terms of the dual occupation number $n_R$.

Figure 3 shows $S_{nl} \times T$ and its $e$-derivative as a function of level position $e$ and temperature difference $\Delta T > 0$. As expected, the zero crossing at the particle-hole symmetric point $e = |U|/2$ persists. Importantly, the counter intuitive features at $e = 0$, $|U|$ also continue to exist. This is indeed suggested by Eq. (11), in which the $e$-dependence enters entirely through the dual occupation $n_R$ determined by repulsive interaction. Specifically, in Fig. 3(c), an increasing $\Delta T$ transforms the steps at $e = 0, |U|$ between the three regimes of $S_{nl}(e) \times T$ with equal $e$-slopes into temperature-broadened transitions between three regimes of different slopes. For $e < 0$ and $e > |U|$, $S_{nl}(e) \times T$ still grows with a slope of 1 as function of $e$, just as the Seebeck coefficient $S(e) \times T$ [see Fig. 1(b)]. This again reflects that transport is effectively governed by single-particle physics (see above discussion on energy-dependent couplings). For levels $0 < e < |U|$ at which two-particle effects are relevant, a linear $e$-dependence of $S_{nl} \times T$ with a larger slope of $\sim 2$ emerges, as can be qualitatively understood from an analysis of the nonlinear charge current (10); a small $T \ll |U|$ and a large $\Delta T \gg |U|$ correspond to a sharp two-particle transition of $n_R = 2 \rightarrow 0$, yet a smooth behavior of $n_L$ as a function of $e$ around.
\( \varepsilon = |U|/2 \). Consequently, fulfilling \( n_{l} = n_{R} \) to achieve \( I = 0 \) for fixed \( \varepsilon \) and \( \mu \) requires a relatively large shift of \( V = \mu - \mu_{l} \). In particular, the slope of 2 of \( S_{\text{nl}}(\varepsilon) \times T = \frac{S_{\text{nl}}}{|U|} \) in the limit \( \Delta T/T \gg 1 \) reflects the sharp change of \( n_{R} \) by 2 at \( \varepsilon = |U|/2 \) due to attractive interaction [see Fig. 1(c)].

Finally, let us consider the power output of the dot. As is well-known,\textsuperscript{41–44} a sharp spectral resonance of a conductor is beneficial for its thermoelectric performance. Hence, quantum dots have been studied as thermoelectric elements operated in the nonlinear regime of large temperature and voltage biases, both theoretically\textsuperscript{6,9,21,22} and experimentally.\textsuperscript{1,20} We now show that also in the presence of strong attractive interaction, finite power output is possible at high efficiencies.

We study the power output \( P = I \times V \) with current \( I \) given by Eq. (10) as well as the efficiency \( \eta = P/J \), where \( J \) is the heat current out of the left (hot) reservoir. Analytical expressions for \( J \) are derived in Ref. 16 for a generic onsite interaction. In Fig. 4(a), we show \( P \) and \( \eta \) as a function of \( V \) for \( \Delta T = -|U| \), \( \Gamma_{L} = \Gamma_{R} = \Gamma \) and for an \( \varepsilon = 1.23|U| \) in the vicinity of the crossover between single- and two-particle regimes, optimized for maximal power output. The power clearly behaves nonmonotonically with a peak at \( |V| \approx \Delta T \). Efficiency \( \eta \) increases with voltage and assumes about 0.6 times the Carnot efficiency \( \eta_{C} = 1 - T_{R}/T_{L} \) at maximum power. These efficiencies are sizable at finite power output, as can clearly be seen in Fig. 4(b), where \( \eta \) and \( P \) are shown for several temperature differences \( \Delta T \). These also show that efficiencies reach the Carnot limit when power is suppressed at large voltages.\textsuperscript{45}

Figures 4(c) and 4(d) show the power \( P_{\text{max}} \) maximized over \( V \) at otherwise fixed parameters and the efficiency \( \eta_{P_{\text{max}}} \) at \( P_{\text{max}} \). Extended regions of \( \varepsilon \)- and \( \Delta T \)-values have sizable power \( P_{\text{max}} \geq \Gamma \). Interestingly, Fig. 4(c) shows that the maximum power is fully suppressed only at \( \varepsilon = |U|/2 \). This can be understood by the fact that the nonlinear thermovoltage \( S_{\text{nl}} \) only disappears at this level position, as shown above. However, in the whole two-particle regime, \( 0 < \varepsilon < |U| \), the power is small compared to the single-particle regime, \( \varepsilon < 0 \) and \( \varepsilon > |U| \). The reason is that the charge relaxation rate \( \gamma_{R} \) entering the current, Eq. (10), is suppressed in this regime by attractive Coulomb blockade.\textsuperscript{27} This leads to low power production.

Important for the performance of the attractive quantum dot as a heat engine is our finding that the efficiency at maximum output power is on the order of the Curzon–Ahlbom bound,\textsuperscript{23} \( \eta_{\text{CA}} = 1 - \sqrt{\left(T_{R}/T_{L}\right)} \), in the whole range in which the output power is sizable. It even reaches this bound close to the \textit{dual} resonances, \( \varepsilon = 0, |U| \), namely, the level positions at which \( n_{R} \) obtained from the dual mapping changes by 1. It is also remarkable that for the finite power output, prominent features appear at the resonances of the real repulsive model.

To conclude, we have analyzed the thermoelectric response of a weakly coupled, single-level quantum dot with attractive interaction together with its performance as a steady-state heat engine. The presented results are expected to be important for future experiments aiming to characterize systems with strong attractive onsite interaction. At the same time, they demonstrate that nanodevices based on quantum dots with attractive interaction can also efficiently convert heat into work.

The most relevant qualitative features that we found are (i) two stepped features in the Seebeck coefficient \( S \) instead of one,\textsuperscript{33} unexpectedly located at the positions for resonances of a repulsive dot (Fig. 1). (ii) Nonlinear Seebeck coefficient \( S_{\text{nl}} \) is constant up to sizeable thermal bias (Fig. 3). (iii) Sharp dip in the maximum power and efficiency at the position \textit{expected} for the attractive dot (Fig. 4). We anticipate these effects in state-of-the-art experiments as, e.g., in quantum dots defined at an oxide interface\textsuperscript{28} where clear features of attractive interaction have already been seen in voltage-driven charge transport measurements. Here, applying a temperature bias would allow to verify our predictions, in particular, due to the available electrical control over the level position. In contrast, nanostructures such as in Ref. 3 allow the magnitude and sign of the \textit{real} interaction to be altered. This would enable a direct comparison between attractive and \textit{real} repulsive quantum dots. Predictions for such a comparison are outlined in the supplementary material. However, these setups would need to be extended to allow for transport measurements.

The remarkable appearance of prominent features at level positions characteristic of a repulsive quantum dot was rationalized with a dual mapping emerging from a dissipative symmetry for master equations. For attractive quantum dots, the role of this dual mapping is particularly important: The dual features with respect to the original attractive system do not appear at special positions, where, e.g., particle-hole symmetry imposes restrictions. Their prominent role could hence not have been predicted straightforwardly in another way.

See the supplementary material for a comparison to a quantum dot with \textit{real} repulsive interaction.
