(Dated: May 8th, 2020)

Planar nanophotonic structures enable broadband, near-unity coupling of emission from quantum dots embedded within, thereby realizing ideal single-photon sources. The efficiency and coherence of the single-photon source is limited by charge noise, which results in the broadening of the emission spectrum. We report suppression of the noise by fabricating photonic crystal waveguides in a gallium arsenide membrane containing quantum dots embedded in a $p-i-n$ diode. Local electrical contacts in the vicinity of the waveguides minimize the leakage current and allow fast electrical control ($\approx 4$ MHz bandwidth) of the quantum dot resonances. Resonant linewidth measurements of 51 quantum dots coupled to the photonic crystal waveguides exhibit near transform-limited emission over a 6 nm wide range of emission wavelengths. Importantly, the local electrical contacts allow independent tuning of multiple quantum dots on the same chip, which together with the transform-limited emission are key components in realizing multiemitter-based quantum information processing.

An on-demand source of indistinguishable single photons is a key building block in a scalable quantum network$^1$. Achieving on-demand operation requires high quantum efficiency of the emitter together with deterministic coupling to a single propagating mode for efficient extraction. Semiconductor quantum dots (QDs) coupled to nanophotonic structures have over the past decade proven to be strong candidates for such a source$^{2-7}$. In particular photonic crystal waveguides (PCWs) enable near-unity coupling of the QD emission to a single propagating mode$^8$ that can be efficiently extracted across a broad spectral range.

The semiconductor environment of the QD usually introduces fluctuations in the form of charge noise, which leads to a decrease of coherence$^9$. The charge noise stems from variations in the electronic states around the QD, which leads to fluctuations in the local electric field. These changes, shift the QD emission energy through the Stark effect and results in a broadening of the emission line. Consequently, the optical linewidth increases significantly above the transform limit determined by the spontaneous emission rate$^{10}$. Charge noise can be suppressed by embedding the QDs in a diode heterostructure$^{11}$. So far transform-limited QDs have been reported in bulk samples$^{12}$, microcavities$^{13}$, and in a multimode nanobeam waveguide$^{14}$. However, in many cases broadband approaches featuring efficient photon-emitter coupling is a major asset, for instance in spin-physics experiments relying on the simultaneous coupling of several optical transitions$^{15}$. While microcavities enable near-unity coupling efficiency, the operable spectral window is limited to the narrow linewidth of the cavity. Multimode waveguides support broadband operation, but the coupling efficiency is limited to $<90\%$. In contrast, PCWs enable broadband near-unity coupling as well as Purcell enhancement of the QD coupled to the waveguide mode. PCWs are composed of air holes etched in a thin membrane (see Fig. 1(a)), resulting in proximity of etched surfaces to the QDs. The proximity of etched surfaces leads to an increase in the charge noise, which has been thoroughly investigated in QDs without electrical contacts$^{16-19}$. In particular, non-contacted QDs embedded in PCWs exhibited line broadening of $>4\times$ the natural linewidth$^{20}$, which may be detrimental for the single-photon source efficiency. Therefore, obtaining transform-limited emission in PCWs is a challenging task and requires low-noise heterostructure semiconductor material and careful nanofabrication in addition to high-quality electrical contacts.

In this work, we establish that electrically-contacted QDs overcome charge noise and enable near transform-limited linewidth in a PCW. Through fabrication of high-quality local electrical contacts, near-ideal diode operation was observed with a short $RC$ time-constant of $<1\mu$s. Linewidths of 79 QDs with resonance frequencies distributed over 6 nm were measured using resonant transmission (RT) of a weak coherent-state and a selection of them compared against the natural linewidth. We observe that at least 65% of the QDs coupled to the PCWs exhibit near transform-limited line shapes.

I. DEVICE FABRICATION AND ELECTRICAL CHARACTERIZATION

A scanning electron microscope (SEM) image of a typical device from the nanofabricated sample is shown in Fig. 1(a). The device consists of a PCW terminated with shallow-etched grating outcouplers, fabricated in a 170 nm-thin sus-
adding an AlAs/GaAs superlattice followed by a 1150nm-thick GaAs substrate. The substrate is prepared for growth us-
membrane is grown using molecular beam epitaxy on a (100)
R series with a PCW of length 20µm. The membrane comprises an ultra-
of 10G T = 0.75
Ga0.25As layer above the QDs is used as a blocking barrier to limit the current to a few nA at a bias voltage of ≈ 1 V, where the QDs can be charged with a single electron.

The sample was cooled to 1.6 K in a closed-cycle helium cryostat with optical and electrical access for QD spectroscopy measurements. The different sections on the sample were wired to independent twisted pair transmission lines in the cryostat. As the n-contacts are not isolated on the sample, we connect them to the common ground of a multichannel low-noise voltage source (V_{rms} < 1 µV). This removes potential ground loops caused by any variations in the parasitic resistance on the sample or the transmission lines. We typically measure an RMS voltage noise of < 200µV up to a bandwidth of 10MHz on the sample transmission lines. This was observed to be limited mostly by the ambient noise picked up
by the twisted pair lines. In another cryostat employing coaxial lines, RMS voltage noise of < 80μV has been measured on a similar sample.

The current-voltage (I-V) curve recorded using a source-meter is shown in the Fig. 1(d). A clear diode turn-on at gate voltage $V_g > 0.7$V is observed with very low leakage current. The sample exhibits a near-ideal I-V curve for a p-i-n diode, with the leakage current limited by the source meter noise in the reverse bias. In the Coulomb blockade regime for QD neutral excitons ($V_g < 1.28$V), the leakage current across the diode is < 1nA, and has thus excellent I-V properties.

II. RESONANT LINEWIDTH MEASUREMENTS

A schematic of the laser transmission experiment in the PCW is shown in Fig. 2(a). The PCWs used in our measurements have a lattice constant of $a = 248$nm and hole radii $r = 70$nm. The PCW is mode-matched to a section with nanobeam waveguide at both ends and terminated with high-efficiency shallow-etched grating couplers for in- and out-coupling of light. Light is launched into the waveguide from the left, and light transmitted through the PCW is collected on the right grating. In Fig. 2(b) a schematic of the optical setup is shown, where a tunable narrow-band laser (bandwidth < 1 MHz) is collimated and imaged to the back focal plane of a wide-field microscope objective. The objective focuses the laser to a spot size which is mode-matched with the in-coupling grating. The light transmitted through the PCW is collected from the right grating using the same microscope objective. The incident laser and collected transmission are separated into different spatial modes using a 5:95 (reflection:transmission) beam splitter, where the transmission arm is used for collection. The collected signal is detected using a superconducting nanowire single-photon detector (SNSPD). The frequency-dependent transmission of the laser through the device at $V_g = 1.0$V, where no QD states are populated due to the high built-in electric field, is shown in Fig. 2(c). The transmission spectrum is normalized to the transmission through a nanobeam waveguide terminated with identical grating out-couplers, to factor out the frequency-dependent diffraction efficiency of the grating out-couplers. A steep cutoff in the transmittance of > 2 orders of magnitude is observed at wavelengths longer than 950.2nm, which corresponds to the band gap of the photonic crystal. This large suppression together with a nearly constant transmission below the cutoff wavelength highlight the excellent photonic properties of the nanofabricated PCWs.

QDs that are efficiently coupled to the PCW exhibit a single-photon non-linearity, where the single-photon component of a weak laser resonant with a QD transition is reflected as illustrated in Fig. 2(a).\textsuperscript{20,27} If the incident photon is detuned from the QD resonance, the interaction with the QD vanishes and the photon is transmitted. This resonant scattering appears as a dip in the frequency-dependent transmission across the PCW. Fig. 2(d) displays such a dip from an RT measurement of a QD, while tuning the applied bias voltage. The charge plateau shows the distinct Coulomb blockade regime for the neutral exciton. Importantly, the charging of the QD occurs at a gate voltage close to the predicted value from bandstructure simulations in contrast to earlier reports.\textsuperscript{28} This agreement is a consequence of the low contact resistance of the sample.

The width of the RT dip, at powers well below the saturation power for the QD, is a reliable measurement of the QD linewidth.\textsuperscript{27} Any charge noise causing the energy levels to shift or fluctuate will degrade the photon-emitter interactions and results in a broadening of measured linewidth. The incident narrow-bandwidth laser power was attenuated to $P = 0.4$μW in the waveguide, which was found to be < 1% of the saturation power of the QDs. At a gate voltage of $V_g = 1.24$V, which corresponds to populating the neutral exciton, the wavelength of the laser is scanned from 944nm to 950nm. The laser wavelength was locked using a wavemeter with a resolution of 50MHz (0.15pm). The 6nm wavelength range near the cutoff was chosen to capture the slow-light regime of light transport in the PCW, which leads to a Purcell enhancement in the radiative decay rate of the QD.\textsuperscript{29} Several QD resonances, identified as RT dips, were recorded in a single continuous wavelength scan, spanning the whole bandwidth of 6nm, with a step size of 100MHz and each RT dip was independently fitted using the model described in Ref. 20. One such RT dip measured from a QD is shown in Fig. 3(a) together with the fit to the model. The asymmetry in the number of sampling points on the positive and negative frequency detuning of the RT resonance is due to the Fano lineshape, which results in a steeper slope on the positive fre-

![Fig. 2](image-url)
frequency side. The Fano lineshape of the RT dip originates from the interference between the QD resonance and a weak reflection from the mode adapters between PCW and the nanobeam waveguides in the device. The linewidth of the QD resonance $\Gamma_{\text{RT}}$ is extracted as the full-width at half-maximum (FWHM) of the fitted curve, which allows to reach values very close to (or even below) the data sampling resolution. The narrowest extracted linewidths may be less precise due to the limited number of data points. For simplicity, the FWHM of the fitted curve is extracted with the Fano parameter omitted (i.e. symmetric lineshape). This approach leads to upper-bound estimates of the linewidth.

For comparison, the transform-limited linewidth $\Gamma$ is extracted from a time-resolved resonance fluorescence (RF) measurement of the QD under pulsed resonant excitation. In this configuration, the QD is excited with a pulsed laser (repetition rate $= 72.6$ MHz; pulse length $\approx 10$ ps). The photons emitted by the QD couple to the propagating PCW mode and are collected at the grating as before. The spatial separation between the QD (excitation laser beam position) and the collection grating ensures a large suppression of the excitation laser in the collection. The RF measurement involves precisely locating the QDs and suppressing the resonant laser scatter, which is challenging and time consuming. Hence, the time-resolved measurements were carried out only on 3 of the QDs at distinct frequencies. Furthermore, time-resolved measurements were also carried out for a few QDs outside the nanostructures (i.e., in bulk) to estimate the homogeneous linewidth of the QDs. Figure 3(b) shows the time-resolved resonance fluorescence of the QD whose RT measurement is shown in Fig. 3(a). The data is modelled with a single-exponential decay convolved with the instrument response function to extract the radiative decay rate $\gamma$. The extracted $\gamma$ is used to estimate the transform-limited linewidth $\Gamma = \gamma / 2 \pi = 460$ MHz. This estimate of $\Gamma$ may be considered a lower bound, since any additional non-radiative processes would increase it, however non-radiative recombination was found to be negligible in photonic-crystal membranes in a previous work. Comparing the natural linewidth against $\Gamma_{\text{RT}}$, we extract that $\Gamma_{\text{RT}} \leq 1.18 \Gamma$, which demonstrates that the noise affecting this specific QD is strongly suppressed. The residual broadening could be attributed to a slow spectral diffusion of the QD resonances (typical timescale of $> 5$ ms in our sample) and nuclear spin noise.

The RT linewidths of the QDs are plotted against their spatial location with respect to the bandedge (waveguide cutoff) as summarized in Fig. 3(a). The transform-limited linewidths estimated from RF measurements are plotted as orange squares, with their corresponding RT linewidth also indicated with squares. The QD whose data is shown in Fig. 3(a-b) is marked with an open circle. Only one QD very close to the bandedge was analyzed due to the difficulty of fitting the RT dips on the steeply rising bandedge. The measured RT dips cover a large range of wavelengths, demonstrating the large bandwidth performance of the PCW. The observed variation in the measured linewidths (120 MHz–1660 MHz) across the QDs is a consequence of the wavelength and spatial position dependence of the Purcell factor in a PCW. Using the radiative decay rate measurements of QDs outside the nanostructure, we estimate the average homogeneous linewidth to be $\Gamma_{\text{hom}} \approx 230$ MHz (dashed line in Fig. 3(c)). The Purcell factor at a specific wavelength is sensitive to the QD dipole orientation and location within the PCW. The wavelength-dependence of the maximum Purcell-enhanced linewidth is extracted from numerical calculations, and plotted as the solid curve in Fig. 3(c). We observe that the maximum Purcell-enhanced linewidth follows the measured $\Gamma_{\text{RT}}$ at all wavelengths as an upper-bound. Few QDs exhibit $\Gamma_{\text{RT}}$ below the homogeneous linewidth, which indicates suppression of the radiative decay rate, and remarkably narrow linewidths are achieved. This observation is also consistent with the PCW's ability to suppress decay rates depending on the QD dipoles location and orientation. The variation of the RT linewidths as a function of distance from the bandedge is therefore explained by the Purcell factor dependence on the dipole orientation and the location of the QDs. For three QDs at spatially and spectral random wavelength locations, we measure the natural linewidth and observe $\Gamma_{\text{RT}} / \Gamma = 1.17$, 1.51, and 1.18, respectively that highlights the excellent charge noise suppression. These three representative measurements together with the observation that $\Gamma_{\text{RT}}$ over 51 QDs is bounded by the maximum Purcell-enhanced linewidth indicates broad-band transform-limited operation of the QDs in PCWs.

A total of 79 QD resonances were found in the frequency scan on two devices, of which 51 (i.e. 65%) were modeled to extract $\Gamma_{\text{RT}}$ as summarized in Fig. 3(d). The linewidths of the remaining 28 QDs were not analyzed due to one of the two factors: (i) very shallow RT dip that could not be robustly fitted or (ii) noisy and spectrally broad RT dip that was affected by slow timescale spectral diffusion. Since the QDs are randomly distributed in the PCW, a selection of them would be weakly coupled to the waveguide mode, either due to their spatial position or the orientation of the dipole. Such QDs exhibit a shallow RT dip due to the weak coupling to the PCW.

We estimate an approximate upper-bound on the distance $d$ from the etched surfaces, beyond which the QDs exhibit transform-limited lineshape as follows. QDs located near an etched surface experience spectral diffusion of the QD resonance due to the fluctuating electric fields caused by charge traps on the surface. This spectral diffusion typically occurs on a time scale of a few milliseconds and is a random process. Therefore, the measured averaged lineshape (over a few seconds) will deviate from the Lorentzian line shape due to the gaussian broadening. Hence, we can assume that the fraction of the QD resonances that are not modelled by a Lorentzian to be a robust indicator for the fraction of QDs located within the distance $d$. The total area in a unit cell of the PCW is $A_{\text{total}}$ (total grey shaded region in Fig. 3(c)). We then define $A_{\text{lim}}$ as the area of the PCW where QDs exhibit near transform-limited linewidth (dark grey area bounded by the dotted circles with distance $d$ to the air holes). Then, by equating the ratio of the areas to the fraction of fitted QDs $f = 51 / 79 = A_{\text{lim}} / A_{\text{total}}$, the limiting distance is estimated to be $d < 43$ nm.

This indicates that a semiconductor heterostructure together with the high-quality electrical contacts achieve optimal oper-
III. ELECTRICAL SWITCHING OF QUANTUM DOTS

Alongside the noise-free operation of QDs, the near-ideal $p$-$i$-$n$ diode $IV$-curve with low contact resistance indicates short $RC$ time constant, which can enable fast electrical switching and control of the QD resonances. We measure the switching time using an RF experiment, where the QD is excited by a narrow-bandwidth continuous-wave laser. The gate voltage $V_g$ across the QD is sinusoidally-modulated around the resonant voltage of the QD. The modulation tunes the QD in and out of resonance with the excitation laser, which in turn modulates the fluorescence intensity. Experimentally, we employ a bias-tee to mix a DC and an AC voltage source, with the DC offset $V_{DC}$ set to the resonant voltage of the QD and the peak-to-peak AC amplitude $V_{AC} = 100\,\text{mV}$, as illustrated in the inset of Fig. 4.

Instead of measuring the modulation in the fluorescence intensity that requires a high-frequency lock-in amplifier, we measure the time-averaged fluorescence (integration time of 1 s). The measured fluorescence intensity with increasing frequency of the AC modulation $f_{AC}$ from 100 Hz to 60 MHz is shown in Fig. 4. As the voltage linewidth of the QD is 1 mV, which is very small in comparison to $V_{AC}$, the QD is resonant with the laser for a very small fraction of the time per cycle. This results in low emission intensity at small $f_{AC}$. As $f_{AC}$ is increased close the $RC$ time constant of the diode, the amplitude of modulation experienced by the QD decreases, which increases the emission intensity. We observe that around $f_{AC} = 3\,\text{MHz}$ the Stark tuning of the QD cannot follow the $V_{AC}$ and the emission intensity saturates to the unmodulated value. The cycle-averaged QD fluorescence intensity $I_{QD}(f_{AC})$ is modeled as

$$I_{QD}(f_{AC}) = I_0 \int_{-A(f_{AC})}^{A(f_{AC})} S(V - V_{DC})dV,$$

where, $A(f_{AC}) = (V_{AC}/2)\exp[-2\pi f_{AC} \tau_{RC}]$. $S(V - V_{DC})$ is the measured voltage response of the QD and $I_0$ is the measured resonance fluorescence intensity without modulation. The model yields an $RC$ time constant $\tau_{RC} = 0.4\,\mu\text{s}$, i.e. a cutoff frequency of $1/(2\pi \tau_{RC}) = 3.98\,\text{MHz}$ for the experimental data. The measured $\tau_{RC}$ together with the 7kΩ series resistance estimated from the $I-V$ curve results in a capacitance $C = 57\,\text{pF}$, which is close to the expected value for the contacted area. The switching speed can be further increased by reducing the contacted area, which in the current configuration covers a full section ($0.5\,\text{mm} \times 3\,\text{mm}$) where all the devices share the same pair of contacts. By dedicating a contact pair to a single PCW with a total area of around $500\,\mu\text{m}^2$, switching speeds of GHz could be reached.

IV. CONCLUSION

In summary, we have demonstrated that charge noise in QDs coupled to PCWs can be largely overcome by employing electrical-contacted QD heterostructures. Statistics on several
QDs reveal that 65% of the QDs exhibit near transform-limited linewidths, which highlight the possibility to realize scalable single-photon sources for quantum information processing\textsuperscript{34}. While some residual surface-induced noise persists, the region of influence of this noise is limited to <43 nm from etched surfaces and could be potentially overcome through surface passivation techniques\textsuperscript{35,36} or through deterministic positioning of QDs\textsuperscript{37–39}. High-speed operation of the p-i-n diode with a cutoff frequency of \(\approx 4\) MHz is demonstrated by measuring the fluorescence from a voltage-modulated QD. The short \(RC\) time constant in combination with near transform-limited linewidths of several QDs paves the way for multi-emitter based quantum information processing protocols, which will greatly benefit from the independent and deterministic control of individual transform-limited emitters\textsuperscript{40–42}.
