Abstract

Machine Learning (ML) seeks to identify and encode bodies of knowledge within provided datasets. However, data encodes subjective content, which determines the possible outcomes of the models trained on it. Because such subjectivity potentially enables marginalisation of parts of society, it is termed (social) ‘bias’ and sought to be removed. In this opinion paper, we contextualise this discourse of bias in the ML community against the subjective choices in the development process. Through a consideration of how choices in data and model development construct subjectivity, or biases that are represented in a model, we argue that addressing and mitigating biases is near-impossible. This is because both data and ML models are objects for which meaning is made in each step of the development pipeline, from data selection over annotation to model training and analysis. Accordingly, we find the prevalent discourse of bias limiting in its ability to address social marginalisation. We recommend to be conscientious of this, and to accept that de-biasing methods only correct for a fraction of biases.

1 Introduction

Machine Learning is concerned with making decisions based on discernible patterns observed in data. Frequently, ML models and the bodies of data they act on are divorced from the context within which they are created, leading to an imposed ‘objectivity’ to these processes and their results. Given that supervised ML seeks to distinguish a set of given bodies of data from one another, and unsupervised ML aims to identify discernible bodies of data in the data provided;¹ both the underlying data and the model applied to it strongly influence what bodies are discovered, and what may be discovered within these bodies. ML models were initially hailed as objective, unimpeded by subjective human biases, and by extension by social marginalisation (ONeil, 2016). However, more and more research suggests that social biases are common in ML models, and that such biases in the underlying data may be exacerbated by the ML models (Zhao et al., 2017). Accordingly, a number of research directions seek to identify (Shah et al., 2020; Bender and Friedman, 2018; Mitchell et al., 2019; Buolamwini and Gebru, 2018), reduce or remove social bias (Zhao et al., 2017; Agarwal et al., 2018) from ML models to protect against further marginalisation. However, previous work frequently assumes a positivist logic of social bias as an optimisation problem, i.e. that bias is a finite resource can be disentangled, isolated, and thus optimised for.

In this article, we revisit these assumptions and take first steps in moving away from solutionist approaches. Drawing on a body of work from feminist Science and Technology Studies (STS) (Haraway, 1988) and examples from Natural Language Processing (NLP), we argue that (a) bias and subjectivity in ML pipelines and models are inescapable and can thus not simply be removed; for which reason (b) an ongoing recognition and reflection on our own positions and the imaginary of objectivity found in subjective realities reflect political choices in the ML pipeline. By contextualising bias in these terms, we seek to shift the surrounding discourse away from bias and its elimination towards subjective positionality and its implications in the ML pipeline. This allows us to investigate how ML practitioners and researchers are complicit in processes of social exclusions in society.

¹Bodies of data are amalgamated entities which exist by virtue of a strict separation from the material bodies they are derived from.
2 Previous Work

Previous work on bias in the computational fields: (i) describes models and datasets with their intended uses and limitations; (ii) quantifies and analyses disparities; or (iii) mitigates biases that are present in models and datasets.

Mapping Bender and Friedman (2018) propose ‘data statements’, a tool to describe and expose representational biases in the processes of developing datasets from collection to annotation. Analogously, Mitchell et al. (2019) propose ‘model cards’ to describe ML models and their behaviour across different populations that might be subject to a given model along with its intended use. Similarly drawing on Haraway (1988), Rettberg (2020) identifies how data is situated and viewed through disembodied positions in the aggregation and display of personal data in mobile applications.

Quantification Shah et al. (2020) propose a mathematical framework quantifying biases in different steps in the NLP pipeline, basing their conceptualisation on work on ethical risks for NLP systems by Hovy and Spruit (2016). More practically, Buolamwini and Gebru (2018) identify how commercial facial recognition systems perform and fail for people with darker skin and women, and perform worst for women with dark skin. Turning to language, Gonen and Goldberg (2019) highlight that methods for debiasing word-embeddings leave traces that allow for reconstructing gendered spaces in ‘debiased’ word embeddings.

Mitigation Two conceptualisations of bias can be found in the large body of work on addressing biases in models (e.g. Agarwal et al., 2018; Romanov et al., 2019; Kulynych et al., 2020; Bolukbasi et al., 2016): one in which bias is imagined as a finite quantity in the model that can be minimised by altering the model’s representation (Agarwal et al., 2018; Romanov et al., 2019); and one which, in a similar vein to our work, accepts the premise that ML, and more broadly optimisation systems, will contain social biases (Kulynych et al., 2020). Working with latter assumption, Kulynych et al. (2020) propose a class of systems that use optimisation logic to counteract the marginalisation a group experiences as the result of ML being applied to them.

3 The ‘God Trick’ of Objectivity

In her seminal STS work, Donna Haraway (1988) calls into question the notion of objectivity, arguing that the production of knowledge is an active process, in which we subjectively construct knowledge based on our very particular, subjective bodies. She argues that an ‘objective’ position like all other positions comes with its own limitations in what it obscures and highlights. In other words, an ‘objective’ position is no less subjective, insofar it privileges the point of view of a particular body marked by subjective social and political meanings and possibilities along lines of race, class, geography, gender etc. However, unlike other ‘subjective’ positions, an ‘objective’ position claims omniscience for itself by denying its particular embodiment, thereby obscuring its own subjective rootedness. This position can then be understood as a disembodied subjective position. By denying the subjectivity of its own body, the objective position elevates itself over other ‘lesser subjective bodies’, thus playing the ‘God trick’ (Haraway, 1988).

Through its disembodiment, the position of objectivity claims to be ‘universal’ and free from embodied socio-political meaning and is therefore applicable in all contexts and can thus be imposed upon all other subjective positions (Mohanty, 1984). Consequently, embodied positions are mired in a particular (as opposed to ‘universal’) context and their particularised experiences of embodied positions can safely be rejected, as accepting them would threaten the omniscient claim of objective study. However, as Haraway (1988) argues, subjectively embodied positions allow for things to be made visible, that are otherwise invisible from the disembodied position. For instance, in the context of n-word usage, an exclusive focus on its derogatory use would imply understanding the word through a disembodied and universalised position, which is a position often (but not always) occupied by the white human body in our world. It is only through an engagement with the particularised experiences of black bodies that the rich cultural meaning crafted in African-American communities reveal themselves (Rahman, 2012).

4 Embodiment in the ML Pipeline

Haraway’s (1988) critique of objectivity makes it possible to understand subjectivity or bias in ML in a way that recognises its potential to create social marginalisation, without inherently reducing
it to a problem which can be optimised. We argue that in ML, the disembodied or objective position exists: (i) in the person designing the experiment and pipeline by developing methods to apply to a data set of others; (ii) in the data which is often disembodied and removed from context, and potentially given adjudication by externalised others that may not be aware of the final use of their work; and (iii) in the model trained on the embodied data subjects.³ We note that once data are ready to be processed by the model, we can consider the model to embody the data, as it is limited to the bodies of knowledge it is presented with. Thus, all other positions, i.e. those not represented in the training data, become disembodied. This can help explain why ML practitioners frequently call for ‘more’ and ‘more diverse’ data (Holstein et al., 2019) to address models that are unjust. However, simply adding more data without addressing whom the datasets embody and how is unlikely to yield the desired result of more just and equitable models.

**Embodiment of the designer** A lack of diversity in ML teams is often attributed as a source of socially biased technologies with corresponding calls for increasing embodying diverse experiences (West et al., 2019). The embodied designers, through data and modelling choices, project an embodiment of self into the technologies they develop. Considering Haraway (1988), it is only through the recognition of different embodiments and promoting them that certain perspectives, understandings, and uses can be achieved.

4.1 Embodiment in Data

Data sets, following Haraway (1988), can be understood as a form of knowledge that does not simply exist but is produced (Gitelman, 2013) through embodied experiences. Subjectivity in datasets can come from a variety of sources, including but not limited to the source of the data (Gitelman and Jackson, 2013), the data sampling method (Shah et al., 2020), the annotation guidelines (Sap et al., 2019), and the selection of annotators (Waseem, 2016; Derczynski et al., 2016). Here, we ground our discussion of how subjectivity manifests itself in ML models through various processes of meaning-making, modelling choices, and data idiosyncrasies, by drawing on examples from NLP.

A common denominator that we seek to highlight, is the subjective and embodied nature of data and subsequent classifications; that by taking a position of objectivity, we cannot do justice to the needs and wants of individual or in fact discernible communities.

**High-level tasks** A range of NLP tasks are highly sensitive to subjective values encoded in the data. This includes high-level tasks that require semantic and pragmatic understanding, e.g. machine translation (MT), dialogue systems, metaphor detection, and sarcasm detection among others. In MT, research has identified a range of issues, including stylistic (Hovy et al., 2020) and gender bias (Vanmassenhove et al., 2018). Issues that pertain to the reinforcement of sexist stereotypes have been the object of academic and public scrutiny. A classic example is the stereotypical translation of English *doctor* (unmarked for gender) to German *Arzt* (marked for masculine), while *nurse* (unmarked) is translated to *Krankenschwester* (feminine). Here, the ‘objective’ position is truly a patriarchal one, which delegates more prestige to men and less to women. The translations above may be correct in certain contexts, but they are not necessarily the only correct ones. This exemplifies the overarching problem that, there is rarely one single ‘gold’ label for a given document, yet most training and evaluation algorithms assume just that.

The issue of highly subjective ‘truths’ in data extends to several other tasks. In the area of text simplification, for instance, numerous datasets postulate that some words, sentences or texts are difficult, while others are simple. These labels are typically provided by a group of human annotators, and while there might be clear majorities for the labelling of certain items, the disembodied position and generalisational power of the annotations will never do justice to the subjective embodiments of text difficulty both across user groups (language learners of different L1 backgrounds, dyslexics, etc.) and just as much within these groups.⁴

For abusive language detection, the causes and effects of embodiment in different stages have been considered in a data set for offensive language use

---

³We highlight here the inherent self-contradiction in ML taking the position of objectivity while tacitly accepting that it is subject to disembodied data as evidenced by the fields of domain adaptation and transfer-learning.

⁴There is some merit in the meta-information on certain task-relevant demographic variables of individual annotators provided in the datasets for the Complex Word Identification 2018 Shared Task. Further, recent work recognises that text simplification systems must build on personalised models (Yimam and Biemann, 2018; Lee and Yeung, 2018; Bingel et al., 2018).
Waseem et al. (2018) argue that a consequence of embodying a white perspective of respectability is that almost all instances of the *n-word* are tagged in the positive classes. Sap et al. (2019) show that by indicating the likely race to the annotators, annotators sought to align their embodiment of ‘offensive’ with the dialect of the author. Further, Davidson et al. (2019) argue that the initially sampled data may itself contain social biases due to a disembodied perspective on slurs.

**Core NLP tasks** However, the issues outlined above are far from limited to high-level NLP tasks. Even core NLP tasks such as part-of-speech (POS) tagging are sensitive to the subjective nature of choices in the ML pipeline. Consider the Penn Treebank tagset (Marcus et al., 1993), the de-facto standard for describing English word classes in NLP. Behind this collectively accepted ‘objective’ truth is a linguistic theory that licenses a certain set of POS tags while not recognising others. The linguistic theory, in turn, is subjective in nature, and typically informed by observations on specific kinds of language. The tagset is thus better suited to describe the kind of English its underlying theory was built on rather than other varieties, sociolects or slang. This becomes more drastically apparent when a tagset developed for English is, for better or worse, forced upon some other languages (Tommasel et al., 2018).

### 4.2 Embodiment in Modelling

While datasets are a large source of how a model may be embodied, ML models also encode which positions, or embodiments, are highlighted. Model behaviour can be seen as being on a spectrum ranging from globally acting models, i.e. models that compound multiple senses of word usage with little regard to its local context; and locally acting models, which seek to embody the datum in the context it is created in, e.g. context-aware models (Garcia et al., 2019; Devlin et al., 2019).

By virtue of the subjective nature of grounding datum in context, there is a large variation in how locally acting models may be developed. Transfer learning can provide one possible avenue for locally acting models. Through transfer learning knowledge produced outside of the target task training set can alter what the model embodies. For instance, should a data set embody the language production within multiple sociolects, a pre-trained language model (Devlin et al., 2019) or mixed-member language models (Blodgett et al., 2016) may provide deeper information about the sociolects in question through using the context of a sentence to identify which context to situate the representation of a document. Beyond language models, multi-task learning models can encode information about the creator of the datum (Benton et al., 2017; Garcia et al., 2019) thus allowing models to take into account the embodiment of the datum. Transfer learning can similarly be applied such to push the model to embody the context the datum is derived from. For instance, Romanov et al. (2019) encode the demographic of a document’s author, deterring models from learning stereotyped representations of marginalised, and in the case of NLP often under-represented, communities. However, much like with globally acting models, transfer learning techniques also engages in processes of disembodiment that must also be actively accounted for, should they be used in efforts to embody the datum.

### 5 Discussion

If subjective choices or biases masquerading as disembodied ‘objective’ positions permeate throughout the ML pipeline – and we argue here that they do – the quest for objectivity or bias-free ML becomes redundant. Rather, such a quest for objectivity or a universal ‘truth’ may even further harm already marginalised social groups by obscuring the dominance of certain bodies over others. Any effort to obscure only deepens the power of dominant groups and hurts marginalised communities further by justifying the imposition of experiences of dominant bodies upon marginalised bodies under the guise of ‘objective’ or ‘bias-free’.

By not recognising the positionality of the designers of ML models and pipelines, practitioners and researchers become complicit how such processes marginalise. Through a recognition of one’s embodiment, the designers of such processes can account for what (and whom) one’s own position, and the models derived from it, allow and penalise, and the political consequences of these.

---

5 As assumed through the prediction of dialect.

6 As sociolects and dialects may not be equally distributed in training data for contextual models (Dunn, 2020), similar issues of which bodies are embodied plague such models (Tan and Celis, 2019).

7 While ‘context’ here is limited to what is in the sentence, language production is situated within a larger socio-political context of society.
As data permeate the ML pipeline, a consideration of how data is embodied can allow for answering specific questions embodied in context; that the contexts which create data are present in every step of the data set creation pipeline; and that as contexts change, so does the applicability of data. Further, models themselves privilege some views over others, and while transfer learning provides some avenues for embodying data in the model, what positions are given space remains a political question.

Thus, by letting go of the idea of fairness as an objective, that can be quantified and biases can be eliminated in a solutionist endeavour without regard for subjective experiences, we are given leave to propose shifting to consider embodiments would ask us to reflect on the subjective experiences that are given voice. Crucially, such a shift would require us to ask and reflect upon which subjective experiences, or rather, the subjective experiences of which bodies we need to account for to give voice to socially marginalised groups.
