GW170817: Observation of Gravitational Waves from a Binary Neutron Star Inspiral

B. P. Abbott et al.

(Received 26 September 2017; revised manuscript received 2 October 2017; published 16 October 2017)

On August 17, 2017 at 12:41:04 UTC the Advanced LIGO and Advanced Virgo gravitational-wave detectors made their first observation of a binary neutron star inspiral. The signal, GW170817, was detected with a combined signal-to-noise ratio of 32.4 and a false-alarm-rate estimate of less than one per 8.0 × 10^4 years. We infer the component masses of the binary to be between 0.86 and 2.26 M⊙, in agreement with masses of known neutron stars. Restricting the component spins to the range inferred in binary neutron stars, we find the component masses to be in the range 1.17–1.60 M⊙, with the total mass of the system 2.74^{+0.04}_{−0.01} M⊙. The source was localized within a sky region of 28 deg² (90% probability) and had a luminosity distance of 40^{+35}_{−6} Mpc, the closest and most precisely localized gravitational-wave signal yet. The association with the γ-ray burst GRB 170817A, detected by Fermi-GBM 1.7 s after the coalescence, corroborates the hypothesis of a neutron star merger and provides the first direct evidence of a link between these mergers and short γ-ray bursts. Subsequent identification of transient counterparts across the electromagnetic spectrum in the same location further supports the interpretation of this event as a neutron star merger. This unprecedented joint gravitational and electromagnetic observation provides insight into astrophysics, dense matter, gravitation, and cosmology.

I. INTRODUCTION

On August 17, 2017, the LIGO-Virgo detector network observed a gravitational-wave signal from the inspiral of two low-mass compact objects consistent with a binary neutron star (BNS) merger. This discovery comes four decades after Hulse and Taylor discovered the first neutron star binary, PSR B1913+16 [1]. Observations of PSR B1913+16 found that its orbit was losing energy due to the emission of gravitational waves, providing the first indirect evidence of their existence [2]. As the orbit of a BNS system shrinks, the gravitational-wave luminosity increases, accelerating the inspiral. This process has long been predicted to produce a gravitational-wave signal observable by ground-based detectors [3–6] in the final minutes before the stars collide [7]. Since the Hulse-Taylor discovery, radio pulsar surveys have found several more BNS systems in our galaxy [8]. Understanding the orbital dynamics of these systems inspired detailed theoretical predictions for gravitational-wave signals from compact binaries [9–13]. Models of the population of compact binaries, informed by the known binary pulsars, predicted that the network of advanced gravitational-wave detectors operating at design sensitivity will observe between one BNS merger every few years to hundreds per year [14–21]. This detector network currently includes three Fabry-Perot-Michelson interferometers that measure spacetime strain induced by passing gravitational waves as a varying phase difference between laser light propagating in perpendicular arms: the two Advanced LIGO detectors (Hanford, WA and Livingston, LA) [22] and the Advanced Virgo detector (Cascina, Italy) [23].

Advanced LIGO’s first observing run (O1), from September 12, 2015, to January 19, 2016, obtained 49 days of simultaneous observation time in two detectors. While two confirmed binary black hole (BBH) mergers were discovered [24–26], no detections or significant candidates had component masses lower than 5M⊙, placing a 90% credible upper limit of 12 600 Gpc⁻³ yr⁻¹ on the rate of BNS mergers [27] (credible intervals throughout this Letter contain 90% of the posterior probability unless noted otherwise). This measurement did not impinge on the range of astrophysical predictions, which allow rates as high as ~10 000 Gpc⁻³ yr⁻¹ [19]. The second observing run (O2) of Advanced LIGO, from November 30, 2016 to August 25, 2017, collected 117 days of simultaneous LIGO-detector observing time. Advanced Virgo joined the O2 run on August 1, 2017. At the time of this publication, two BBH detections have been announced [28,29] from the O2 run, and analysis is still in progress.

Toward the end of the O2 run a BNS signal, GW170817, was identified by matched filtering [7,30–33] the data against post-Newtonian waveform models [34–37]. This gravitational-wave signal is the loudest yet observed, with a combined signal-to-noise ratio (SNR) of 32.4 [38]. After

∼100 s (calculated starting from 24 Hz) in the detectors’ sensitive band, the inspiral signal ended at 12:41:04.4 UTC. In addition, a γ-ray burst was observed 1.7 s after the coalescence time [39–45]. The combination of data from the LIGO and Virgo detectors allowed a precise sky position localization to an area of 28 deg². This measurement enabled an electromagnetic follow-up campaign that identified a counterpart near the galaxy NGC 4993, consistent with the localization and distance inferred from gravitational-wave data [46–50].

From the gravitational-wave signal, the best measured combination of the masses is the chirp mass [51] $M = 1.188^{+0.004}_{-0.002} M_\odot$. From the union of 90% credible intervals obtained using different waveform models (see Sec. IV for details), the total mass of the system is between 2.73 and 3.29 $M_\odot$. The individual masses are in the broad range of 0.86 to 2.26 $M_\odot$, due to correlations between their uncertainties. This suggests a BNS as the source of the gravitational-wave signal, as the total masses of known BNS systems are between 2.57 and 2.88 $M_\odot$ with components between 1.17 and ∼1.6 $M_\odot$ [52]. Neutron stars in general have precisely measured masses as large as 2.01 ± 0.04 $M_\odot$ [53], whereas stellar-mass black holes found in binaries in our galaxy have masses substantially greater than the components of GW170817 [54–56].

Gravitational-wave observations alone are able to measure the masses of the two objects and set a lower limit on their compactness, but the results presented here do not exclude objects more compact than neutron stars such as quark stars, black holes, or more exotic objects [57–61]. The detection of GRB 170817A and subsequent electromagnetic emission demonstrates the presence of matter. Moreover, although a neutron star–black hole system is not ruled out, the consistency of the mass estimates with the dynamically measured masses of known neutron stars in binaries, and their inconsistency with the masses of known black holes in galactic binary systems, suggests the source was composed of two neutron stars.

II. DATA

At the time of GW170817, the Advanced LIGO detectors and the Advanced Virgo detector were in observing mode. The maximum distances at which the LIGO-Livingston and LIGO-Hanford detectors could detect a BNS system (SNR = 8), known as the detector horizon [32,62,63], were 218 Mpc and 107 Mpc, while for Virgo the horizon was 58 Mpc. The GEO600 detector [64] was also operating at the time, but its sensitivity was insufficient to contribute to the analysis of the inspiral. The configuration of the detectors at the time of GW170817 is summarized in [29].

A time-frequency representation [65] of the data from all three detectors around the time of the signal is shown in Fig 1. The signal is clearly visible in the LIGO-Hanford and LIGO-Livingston data. The signal is not visible in the Virgo data due to the lower BNS horizon and the direction of the source with respect to the detector’s antenna pattern.

Figure 1 illustrates the data as they were analyzed to determine astrophysical source properties. After data collection, several independently measured terrestrial contributions to the detector noise were subtracted from the LIGO data using Wiener filtering [66], as described in [67–70]. This subtraction removed calibration lines and 60 Hz ac power mains harmonics from both LIGO data streams. The sensitivity of the LIGO-Hanford detector was particularly improved by the subtraction of laser pointing noise; several broad peaks in the 150–800 Hz region were effectively removed, increasing the BNS horizon of that detector by 26%.
Additionally, a short instrumental noise transient appeared in the LIGO-Livingston detector 1.1 s before the coalescence time of GW170817 as shown in Fig. 2. This transient noise, or glitch [71], produced a very brief (less than 5 ms) saturation in the digital-to-analog converter of the feedback signal controlling the position of the test masses. Similar glitches are registered roughly once every few hours in each of the LIGO detectors with no temporal correlation between the LIGO sites. Their cause remains unknown. To mitigate the effect on the results presented in Sec. III, the search analyses applied a window function to zero out the data around the glitch [72,73], following the treatment of other high-amplitude glitches used in the O1 analysis [74]. To accurately determine the properties of GW170817 (as reported in Sec. IV) in addition to the noise subtraction described above, the glitch was modeled with a time-frequency wavelet reconstruction [75] and subtracted from the data, as shown in Fig. 2.

Following the procedures developed for prior gravitational-wave detections [29,78], we conclude there is no environmental disturbance observed by LIGO environmental sensors [79] that could account for the GW170817 signal.

The Virgo data, used for sky localization and an estimation of the source properties, are shown in the bottom panel of Fig. 1. The Virgo data are nonstationary above 150 Hz due to scattered light from the output optics modulated by alignment fluctuations and below 30 Hz due to seismic noise from anthropogenic activity. Occasional noise excess around the European power mains frequency of 50 Hz is also present. No noise subtraction was applied to the Virgo data prior to this analysis. The low signal amplitude observed in Virgo significantly constrained the sky position, but meant that the Virgo data did not contribute significantly to other parameters. As a result, the estimation of the source’s parameters reported in Sec. IV is not impacted by the nonstationarity of Virgo data at the time of the event. Moreover, no unusual disturbance was observed by Virgo environmental sensors.

Data used in this study can be found in [80].

### III. DETECTION

GW170817 was initially identified as a single-detector event with the LIGO-Hanford detector by a low-latency binary-coalescence search [81–83] using template waveforms computed in post-Newtonian theory [11,13,36,84]. The two LIGO detectors and the Virgo detector were all taking data at the time; however, the saturation at the LIGO-Livingston detector prevented the search from registering a simultaneous event in both LIGO detectors, and the low-latency transfer of Virgo data was delayed.

Visual inspection of the LIGO-Hanford and LIGO-Livingston detector data showed the presence of a clear, long-duration chirp signal in time-frequency representations of the detector strain data. As a result, an initial alert was generated reporting a highly significant detection of a binary neutron star signal [85] in coincidence with the independently observed γ-ray burst GRB 170817A [39–41].

A rapid binary-coalescence reanalysis [86,87], with the time series around the glitch suppressed with a window function [73], as shown in Fig. 2, confirmed the presence of a significant coincident signal in the LIGO detectors. The source was rapidly localized to a region of 31 deg$^2$, shown in Fig. 3, using data from all three detectors [88]. This sky map was issued to observing partners, allowing the identification of an electromagnetic counterpart [46,48,50,77].

The combined SNR of GW170817 is estimated to be 32.4, with values 18.8, 26.4, and 2.0 in the LIGO-Hanford,
LIGO-Livingston, and Virgo data respectively, making it the loudest gravitational-wave signal so far detected. Two matched-filter binary-coalescence searches targeting sources with total mass between 2 and 500 $M_{\odot}$ in the detector frame were used to estimate the significance of this event [9,12,30,73,81–83,86,87,91–97]. The searches analyzed 5.9 days of LIGO data between August 13, 2017 02:00 UTC and August 21, 2017 01:05 UTC. Events are assigned a detection-statistic value that ranks their probability of being a gravitational-wave signal. Each search uses a different method to compute this statistic and measure the search background—the rate at which detector noise produces events with a detection-statistic value equal to or higher than the candidate event.

GW170817 was identified as the most significant event in the 5.9 days of data, with an estimated false alarm rate of one in $1.1 \times 10^6$ years with one search [81,83], and a consistent bound of less than one in $8.0 \times 10^3$ years for the other [73,86,87]. The second most significant signal in this analysis of 5.9 days of data is GW170814, which has a combined SNR of 18.3 [29]. Virgo data were not used in these significance estimates, but were used in the sky localization of the source and inference of the source properties.

**IV. SOURCE PROPERTIES**

General relativity makes detailed predictions for the inspiral and coalescence of two compact objects, which may be neutron stars or black holes. At early times, for low orbital and gravitational-wave frequencies, the chirplike time evolution of the frequency is determined primarily by a specific combination of the component masses $m_1$ and $m_2$, the chirp mass $M = (m_1 m_2)^{3/5}(m_1 + m_2)^{-1/5}$. As the orbit shrinks and the gravitational-wave frequency grows rapidly, the gravitational-wave phase is increasingly influenced by relativistic effects related to the mass ratio $q = m_2/m_1$, where $m_1 \geq m_2$, as well as spin-orbit and spin-spin couplings [98].

The details of the objects’ internal structure become important as the orbital separation approaches the size of the bodies. For neutron stars, the tidal field of the companion induces a mass-quadrupole moment [99,100] and accelerates the coalescence [101]. The ratio of the induced quadrupole moment to the external tidal field is proportional to the tidal deformability (or polarizability) $\Lambda = (2/3)k_2[[e^2/G](R/m)]^2$, where $k_2$ is the second Love number and $R$ is the stellar radius. Both $R$ and $k_2$ are fixed for a given stellar mass $m$ by the equation of state (EOS) for neutron-star matter, with $k_2 = 0.05-0.15$ for realistic neutron stars [102–104]. Black holes are expected to have $k_2 = 0$ [99,105–109], so this effect would be absent.

As the gravitational-wave frequency increases, tidal effects in binary neutron stars increasingly affect the phase and become significant above $f_{GW} = 600$ Hz, so they are potentially observable [103,110–116]. Tidal deformabilities correlate with masses and spins, and our measurements are sensitive to the accuracy with which we describe the point-mass, spin, and tidal dynamics [113,117–119]. The point-mass dynamics has been calculated within the post-Newtonian framework [34,36,37], effective-one-body formalism [10,120–125], and with a phenomenological approach [126–131]. Results presented here are obtained using a frequency domain post-Newtonian waveform model [30] that includes dynamical effects from tidal interactions [132], point-mass spin-spin interactions [34,37,133,134], and couplings between the orbital angular momentum and the orbit-aligned dimensionless spin components of the stars $\chi_c$ [92].

The properties of gravitational-wave sources are inferred by matching the data with predicted waveforms. We perform a Bayesian analysis in the frequency range 30–2048 Hz that includes the effects of the $1\sigma$ calibration uncertainties on the received signal [135,136] (< 7% in amplitude and 3° in phase for the LIGO detectors [137] and 10% and 1° for Virgo at the time of the event). Unless otherwise specified, bounds on the properties of GW170817 presented in the text and in Table I are 90% posterior probability intervals that enclose systematic differences from currently available waveform models.

To ensure that the applied glitch mitigation procedure previously discussed in Sec. II (see Fig. 2) did not bias the estimated parameters, we added simulated signals with known parameters to data that contained glitches analogous
to the one observed at the LIGO-Livingston detector during GW170817. After applying the glitch subtraction technique, we found that the bias in recovered parameters relative to their known values was well within their uncertainties. This can be understood by noting that a small time cut out of the coherent integration of the phase evolution has little impact on the recovered parameters. To corroborate these results, the test was also repeated with a window function applied, as shown in Fig. 2 [73].

The source was localized to a region of the sky 28 deg² in area, and 380 Mpc³ in volume, near the southern end of the constellation Hydra, by using a combination of the timing, phase, and amplitude of the source as observed in the three detectors [138,139]. The third detector, Virgo, was essential in localizing the source to a single region of the sky, as shown in Fig. 3. The small sky area triggered a successful follow-up campaign that identified an electromagnetic counterpart [50].

The luminosity distance to the source is $40^{+3}_{-14}$ Mpc, the closest ever observed gravitational-wave source and, by association, the closest short $\gamma$-ray burst with a distance measurement [45]. The distance measurement is correlated with the inclination angle $\cos \theta_{JN} = \mathbf{J} \cdot \mathbf{N}$, where $\mathbf{J}$ is the unit vector in the direction of the total angular momentum of the system and $\mathbf{N}$ is that from the source towards the observer [140]. We find that the data are consistent with an antialigned source: $\cos \theta_{JN} \leq -0.54$, and the viewing angle $\Theta = \min(\theta_{JN}, 180° - \theta_{JN})$ is $\Theta \leq 56°$. Since the luminosity distance of this source can be determined independently of the gravitational wave data alone, we can use the association with NGC 4993 to break the distance degeneracy with $\cos \theta_{JN}$. The estimated Hubble flow velocity near NGC 4993 of $3017 \pm 166$ km s⁻¹ [141] provides a redshift, which in a flat cosmology with $H_0 = 67.90 \pm 0.55$ km s⁻¹ Mpc⁻¹ [90], constrains $\cos \theta_{JN} < -0.88$ and $\Theta < 28°$. The constraint varies with the assumptions made about $H_0$ [141].

From the gravitational-wave phase and the $\sim 3000$ cycles in the frequency range considered, we constrain the chirp mass in the detector frame to be $M_{\text{det}} = 1.1977^{+0.0008}_{-0.0003} M_\odot$ [51]. The mass parameters in the detector frame are related to the rest-frame masses of the source by its redshift $z$ as $m_{\text{det}} = m(1+z)$ [142]. Assuming the above cosmology [90], and correcting for the motion of the Solar System Barycenter with respect to the Cosmic Microwave Background [143], the gravitational-wave distance measurement alone implies a cosmological redshift of $0.008^{+0.002}_{-0.003}$, which is consistent with that of NGC 4993 [50,141,144,145]. Without the host galaxy, the uncertainty in its luminosity distance. Independent of the waveform model or the choice of priors, described below, the source-frame chirp mass is $M = 1.188^{+0.004}_{-0.002} M_\odot$.

While the chirp mass is well constrained, our estimates of the component masses are affected by the degeneracy between mass ratio $q$ and the aligned spin components $\chi_z$ and $\chi_{2z}$ [38,146–150]. Therefore, the estimates of $q$ and the component masses depend on assumptions made about the admissible values of the spins. While $\chi < 1$ for black holes, and quark stars allow even larger spin values, realistic NS equations of state typically imply more stringent limits. For the set of EOS studied in [151] $\chi < 0.7$, although other EOS can exceed this bound. We began by assuming $|\chi| \leq 0.89$, a limit imposed by available rapid waveform models, with an isotropic prior on the spin direction. With these priors we recover $q \in (0.4, 1.0)$ and a constraint on the effective aligned spin of the system [127,152] of $\chi_{\text{eff}} \in (-0.01, 0.17)$. The aligned spin components are consistent with zero, with stricter bounds than in previous BBH observations [26,28,29]. Analysis using the effective precessing phenomenological waveforms of [128], which do not contain tidal effects, demonstrates that spin components in the orbital plane are not constrained.
We also recover the mass ratio \( m_2/m_1 \) in the rest frame of the source for the low-spin scenario (\( |\chi| < 0.05 \), blue) and the high-spin scenario (\( |\chi| < 0.89 \), red). The colored contours enclose 90% of the probability from the joint posterior probability density function for \( m_1 \) and \( m_2 \). The shape of the two-dimensional posterior is determined by a line of constant \( \chi \). The widths of the marginal distributions (shown on axes, dashed lines) enclose 90% probability from the joint posterior probability density function.

From \( \mathcal{M} \) and \( q \), we obtain a measure of the component masses \( m_1 \in (1.36, 2.26)M_\odot \) and \( m_2 \in (0.86, 1.36)M_\odot \), shown in Fig. 4. As discussed in Sec. I, these values are within the range of known neutron-star masses and below those of known black holes. In combination with electromagnetic observations, we regard this as evidence of the BNS nature of GW170817.

The fastest-spinning known neutron star has a dimensionless spin \( \lesssim 0.4 \) [153], and the possible BNS J1807-2500B has spin \( \lesssim 0.2 \) [154], after allowing for a broad range of equations of state. However, among BNS that will merge within a Hubble time, PSR J0737-3039A [155] has the most extreme spin, less than \( \sim 0.04 \) after spin-down is extrapolated to merger. If we restrict the spin magnitude in our analysis to \( |\chi| \leq 0.05 \), consistent with the observed population, we recover the mass ratio \( q \in (0.7, 1.0) \) and component masses \( m_1 \in (1.36, 1.60)M_\odot \) and \( m_2 \in (1.17, 1.36)M_\odot \) (see Fig. 4). We also recover \( \chi_{\text{eff}} \in (-0.01, 0.02) \), where the upper limit is consistent with the low-spin prior.

Our first analysis allows the tidal deformabilities of the high-mass and low-mass component, \( \Lambda_1 \) and \( \Lambda_2 \), to vary independently. Figure 5 shows the resulting 90% and 50% contours on the posterior distribution with the post-Newtonian waveform model for the high-spin and low-spin priors. As a comparison, we show predictions coming from a set of candidate equations of state for neutron-star matter [156–160], generated using fits from [161]. All EOS support masses of \( 2.01 \pm 0.04M_\odot \). Assuming that both components are neutron stars described by the same equation of state, a single function \( \Lambda(m) \) is computed from the static \( \epsilon = 2 \) perturbation of a Tolman-Oppenheimer-Volkoff solution [103]. The shaded regions in Fig. 5 represent the values of the tidal deformabilities \( \Lambda_1 \) and \( \Lambda_2 \) generated using an equation of state from the 90% most probable fraction of the values of \( m_1 \) and \( m_2 \), consistent with the posterior shown in Fig. 4. We find that our constraints on \( \Lambda_1 \) and \( \Lambda_2 \) disfavor equations of state that predict less compact stars, since the mass range we recover generates \( \Lambda \) values outside the 90% probability region. This is consistent with radius constraints from x-ray observations of neutron stars [162–166]. Analysis methods, in development, that \textit{a priori} assume the same EOS governs both stars should improve our constraints [167].

To leading order in \( \Lambda_1 \) and \( \Lambda_2 \), the gravitational-wave phase is determined by the parameter

\[
\tilde{\Lambda} = \frac{16 (m_1 + 12m_2)m_1^4\Lambda_1 + (m_2 + 12m_1)m_2^4\Lambda_2}{(m_1 + m_2)^8}
\]

[101,117]. Assuming a uniform prior on \( \tilde{\Lambda} \), we place a 90% upper limit of \( \tilde{\Lambda} \leq 800 \) in the low-spin case and \( \tilde{\Lambda} \leq 700 \) in the high-spin case. We can also constrain the function \( \Lambda(m) \) more directly by expanding \( \Lambda(m) \) linearly about \( m = 1.4M_\odot \) (as in [112,115]), which gives \( \Lambda(1.4M_\odot) \leq 1400 \) for the high-spin prior and \( \Lambda(1.4M_\odot) \leq 800 \) for the low-spin prior. A 95% upper bound inferred with the low-spin prior, \( \Lambda(1.4M_\odot) \leq 970 \), begins to compete with the 95% upper bound of 1000 derived from x-ray observations in [168].

Since the energy emitted in gravitational waves depends critically on the EOS of neutron-star matter, with a wide range consistent with constraints above, we are only able to place a lower bound on the energy emitted before the onset of strong tidal effects at \( f_{\text{GW}} \sim 600 \text{Hz} \) as \( E_{\text{rad}} > 0.025M_\odot c^2 \). This is consistent with \( E_{\text{rad}} \) obtained from numerical simulations and fits for BNS systems consistent with GW170817 [114,169–171].

We estimate systematic errors from waveform modeling by comparing the post-Newtonian results with parameters recovered using an effective-one-body model [124] augmented with tidal effects extracted from numerical relativity with hydrodynamics [172]. This does not change the 90% credible intervals for component masses and effective spin under low-spin priors, but in the case of high-spin priors, we obtain the more restrictive \( m_1 \in (1.36, 1.93)M_\odot \), \( m_2 \in (0.99, 1.36)M_\odot \), and \( \chi_{\text{eff}} \in (0.0, 0.09) \). Recovered tidal deformabilities indicate shifts in the posterior distributions towards smaller values, with upper bounds for \( \tilde{\Lambda} \) and \( \Lambda(1.4M_\odot) \) reduced by a factor of roughly (0.8, 0.8) in the
Preliminary comparisons with waveform models under development \[171,173–177\] also suggest the post-Newtonian model used will systematically overestimate the value of the tidal deformabilities. Therefore, based on our current understanding of the physics of neutron stars, we consider the post-Newtonian results presented in this Letter to be conservative upper limits on tidal deformability. Refinements should be possible as our knowledge and models improve.

V. IMPLICATIONS

A. Astrophysical rate

Our analyses identified GW170817 as the only BNS-mass signal detected in O2 with a false alarm rate below \[1/100 \text{ yr}\]. Using a method derived from \[27,178,179\], and assuming that the mass distribution of the components of BNS systems is flat between 1 and \[2 M_\odot\] and their dimensionless spins are below 0.4, we are able to infer the local coalescence rate density \(R\) of BNS systems. Incorporating the upper limit of 12600 Gpc\(^{-3}\) yr\(^{-1}\) from O1 as a prior, \(R = 1540^{+3200}_{-1220} \text{ Gpc}^{-3} \text{ yr}^{-1}\). Our findings are consistent with the rate inferred from observations of galactic BNS systems \[19,20,155,180\].

From this inferred rate, the stochastic background of gravitational wave signals produced by unresolved BNS mergers throughout the history of the Universe should be comparable in magnitude to the stochastic background produced by BBH mergers \[181,182\]. As the advanced detector network improves in sensitivity in the coming years, the total stochastic background from BNS and BBH mergers should be detectable \[183\].

B. Remnant

Binary neutron star mergers may result in a short- or long-lived neutron star remnant that could emit gravitational waves following the merger \[184–190\]. The ringdown of a black hole formed after the coalescence could also produce gravitational waves, at frequencies around 6 kHz, but the reduced interferometer response at high frequencies makes their observation unfeasible. Consequently, searches have been made for short (tens of ms) and intermediate duration (\(\leq 500 \text{ s}\)) gravitational-wave signals from a neutron star remnant at frequencies up to 4 kHz \[75,191,192\]. For the latter, the data examined start at the time of the coalescence and extend to the end of the observing run on August 25, 2017. With the time scales and methods considered so far \[193\], there is no evidence of a postmerger signal of...
astrophysical origin. However, upper limits placed on the strength of gravitational-wave emission cannot definitively rule out the existence of a short- or long-lived postmerger neutron star. The implications of various postmerger scenarios are explored in [45,193].

C. Tests of gravity

GRB 170817A was observed 1.7 s after GW170817. Combining this delay with the knowledge of the source luminosity distance, strong constraints are placed on the fundamental physics of gravity. The observed arrival times are used to investigate the speed of gravity, Lorentz invariance, and tests of the equivalence principle through the Shapiro time delay, as reported in [45].

We also expect the much longer duration of the BNS signal compared to previous BBH gravitational-wave sources to yield significantly improved constraints when testing for waveform deviations from general relativity using a parametrized waveform expansion [194], especially at low post-Newtonian orders. Placing these bounds requires a deep understanding of the systematic uncertainties resulting from waveform modeling and data conditioning, and is the subject of ongoing investigations.

D. Cosmology

The gravitational-wave signal gives a direct measurement of the luminosity distance of the source, which, along with a redshift measurement, can be used to infer cosmological parameters independently of the cosmic distance ladder [141,195]. Using the association with the galaxy NGC 4993 and the luminosity distance directly measured from the gravitational-wave signal, the Hubble constant is inferred to be $H_0 = 70^{+12}_{-8}$ $\text{km s}^{-1} \text{Mpc}^{-1}$ [141] (most probable value and minimum 68.3% probability range, which can be compared to the value from Planck $H_0 = 67.90 \pm 0.55$ $\text{km s}^{-1} \text{Mpc}^{-1}$ [90]). Alternatively, we may assume the cosmology is known and use the association with NGC 4993 to constrain the luminosity distance of the source, in which case the gravitational-wave measurement of the inclination angle of the source is significantly improved, with consequences for the $\gamma$-ray burst opening angle and related physics [45].

VI. CONCLUSIONS

In this Letter we have presented the first detection of gravitational waves from the inspiral of a binary neutron star system. Gravitational-wave event GW170817, observed and localized by the two Advanced LIGO detectors and the Advanced Virgo detector, is the loudest gravitational-wave signal detected to date. This coalescence event was followed by a short burst of $\gamma$ rays observed with the Fermi Gamma-Ray Burst Monitor [39–42] and INTEGRAL [43,44]. The coincident observation of a gravitational-wave signal and a $\gamma$-ray burst appears to confirm the long-held hypothesis that BNS mergers are linked to short-$\gamma$-ray bursts [196,197]. Subsequent observations have determined the location of the source and followed its evolution through the electromagnetic spectrum [50].

Detailed analyses of the gravitational-wave data, together with observations of electromagnetic emissions, are providing new insights into the astrophysics of compact binary systems and $\gamma$-ray bursts, dense matter under extreme conditions, the nature of gravitation, and independent tests of cosmology. Less than two years after the debut of gravitational-wave astronomy, GW170817 marks the beginning of a new era of discovery.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the support of the United States National Science Foundation (NSF) for the construction and operation of the LIGO Laboratory and Advanced LIGO as well as the Science and Technology Facilities Council (STFC) of the United Kingdom, the Max-Planck-Society (MPS), and the State of Niedersachsen, Germany for support of the construction of Advanced LIGO and construction and operation of the GEO600 detector. Additional support for Advanced LIGO was provided by the Australian Research Council. The authors gratefully acknowledge the Italian Istituto Nazionale di Fisica Nucleare (INFN), the French Centre National de la Recherche Scientifique (CNRS), and the Foundation for Fundamental Research on Matter supported by the Netherlands Organisation for Scientific Research, for the construction and operation of the Virgo detector and the creation and support of the EGO consortium. The authors also gratefully acknowledge research support from these agencies as well as by the Council of Scientific and Industrial Research of India, the Department of Science and Technology, India, the Science & Engineering Research Board (SERB), India, the Ministry of Human Resource Development, India, the Spanish Agencia Estatal de Investigación, the Vicepresidència i Conselleria d’Innovació, Recerca i Turisme and the Conselleria d’Educació i Universitat del Govern de les Illes Balears, the Conselleria d’Educació, Investigació, Cultura i Esport de la Generalitat Valenciana, the National Science Centre of Poland, the Swiss National Science Foundation (SNSF), the Russian Foundation for Basic Research, the Russian Science Foundation, the European Commission, the European Regional Development Funds (ERDF), the Royal Society, the Scottish Funding Council, the Scottish Universities Physics Alliance, the Hungarian Scientific Research Fund (OTKA), the Lyon Institute of Origins (LIO), the National Research, Development and Innovation Office Hungary (NKFI), the National Research Foundation of Korea, Industry Canada and the Province of Ontario through the Ministry of Economic Development and Innovation, the Natural Science and Engineering Research Council Canada, the Canadian Institute for Advanced Research, the Brazilian
Ministry of Science, Technology, Innovations, and Communications, the International Center for Theoretical Physics South American Institute for Fundamental Research (ICTP-SAIFR), the Research Grants Council of Hong Kong, the National Natural Science Foundation of China (NSFC), the Leverhulme Trust, the Research Corporation, the Ministry of Science and Technology (MOST), Taiwan and the Kavli Foundation. The authors gratefully acknowledge the support of the NSF, STFC, MPS, INFN, CNRS and the State of Niedersachsen, Germany for provision of computational resources. This research has made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.
