Twisted bilayer graphene (TBG) provides a unique framework to elucidate the interplay between strong correlations and topological phenomena in two-dimensional systems. The existence of multiple electronic degrees of freedom—charge, spin, and valley—gives rise to a plethora of possible ordered states and instabilities. Identifying which of them are realized in the regime of strong correlations is fundamental to shed light on the nature of the superconducting and correlated insulating states observed in the TBG experiments. Here, we use unbiased, sign-problem-free quantum Monte Carlo simulations to solve an effective interacting lattice model for TBG at charge neutrality. Besides the usual cluster Hubbard-like repulsion, this model also contains an assisted-hopping interaction that emerges due to the nontrivial topological properties of TBG. Such a nonlocal interaction fundamentally alters the phase diagram at charge neutrality, gapping the Dirac cones even for infinitesimally small interactions. As the interaction strength increases, a sequence of different correlated insulating phases emerge, including a quantum valley Hall state with topological edge states, an intervalley-coherent insulator, and a valence bond solid. The charge-neutrality correlated insulating phases discovered here provide the sought-after reference states needed for a comprehensive understanding of the insulating states at integer fillings and the proximate superconducting states of TBG.

DOI: 10.1103/PhysRevX.11.011014

I. INTRODUCTION

The recent discovery of correlated insulating and superconducting phases in twisted bilayer graphene (TBG) [1–3] and other moiré systems [4–7] sparked a flurry of activity to elucidate and predict the electronic quantum phases realized in their phase diagrams [8–68]. Because the low-energy bands of TBG have a very small bandwidth, of about 10 meV at the magic twist angle, the Coulomb interaction, which is of the order of 25 meV, is expected to play a fundamental role in shaping the phase diagram [1,13,20,23]. Indeed, insulating states have been reported at all commensurate fillings of the moiré superlattice [10], signaling the importance of strong correlations. Besides correlations, topological phenomena have also been reported, including a quantum anomalous Hall (QAH) phase [69,70].

An important issue is the nature of the quantum ground state at charge neutrality, characterized in real space by four electrons per moiré unit cell and in momentum space by Dirac points at the Fermi level. Experimentally, a large...
charge gap characteristic of an insulating state was reported in transport measurements in Ref. [10] and in STM measurements in Ref. [11], despite no obvious alignment with the underlying hBN layer. The fact that this gap is not observed in all devices has been attributed to inhomogeneity [10]. Theoretically, because the electronic states in TBG have several degrees of freedom—spin, valley, and sublattice—various possible ground states can emerge. Indeed, Hartree-Fock calculations of the continuum model at charge neutrality found various possible states, such as orbital-magnetization density waves, valley polarized states, and states that spontaneously break the threefold rotational symmetry of the moiré lattice [44,48,49,53,59,61,71,72]. To distinguish among these different possibilities, and to search for novel ordered states in TBG, it is desirable to employ a method that is not only unbiased but that can also handle strong correlations.

Large-scale quantum Monte Carlo (QMC) simulations provide an optimal tool, limited only by the finite lattice sizes. Although such a limitation makes it impossible to simulate a model with thousands of carbon atoms per moiré unit cell, it is very well suited to solve lattice models on the moiré length scale. At charge neutrality, the noninteracting part of the model has only Dirac points at the Fermi level. The crucial part of the model, however, is the interacting part, which governs the system’s behavior in the strong-coupling regime. At first sight, based on the analogy with other strongly correlated models, it would seem sufficient to consider a cluster Hubbard-like repulsion as the main interaction of the problem. Previously, some of us used QMC to simulate this model, which does not suffer from the infamous fermionic sign problem [63,64]. The result was a variety of valence-bond insulating states, which, however, only onset at relatively large values of the interaction $U$, of the order of several times the bandwidth $W$. Below these large values, the system remained in the Dirac semimetal phase.

However, microscopically, the full interaction of the lattice model can be derived from projecting the screened Coulomb repulsion on the Wannier states (WSs) of TBG. The latter turn out to be quite different than in other correlated materials, as they have nodes on the sites of the moiré honeycomb superlattice and a three-peak structure that overlaps with Wannier functions centered at other sites [20,21,23]. Recent work has shown that this leads to the emergence of an additional and sizable nonlocal interaction, of the form of an assisted-hopping term [37,54]. This new interaction ultimately arises from the fact that, in a lattice model, the symmetries of the continuum model cannot all be implemented locally, a phenomenon dubbed Wannier obstruction [23]. Therefore, the assisted-hopping interaction is not a simple perturbation but a direct and unavoidable manifestation of the nontrivial topological properties of TBG. This important aspect of the TBG was not taken into consideration in the previous QMC simulations.

In this paper, we make this important step forward by studying the impact of the assisted-hopping interaction on the ground state of TBG at charge neutrality via sign-problem-free QMC simulations. We find that such a term qualitatively changes the phase diagram, as compared to the case where only the cluster Hubbard interaction is included. In particular, the Dirac semimetal phase is no longer stable but is gapped already at weak coupling. We show that this gap is a manifestation of a quantum valley Hall (QVH) state, characterized by topological edge states. We confirm this weak-coupling result by unrestricted Hartree-Fock (HF) calculations of the same model simulated by QMC. The HF calculations, well suited for weak interactions, also show that the QVH state is a robust property of the weak-coupling regime and is directly connected to the assisted-hopping term. As the interaction strength increases, a different type of insulating phase arises, displaying inter-valley coherence (IVC) order. This on-site IVC order breaks the spin-valley SU(4) symmetry of the interacting part of the model, resembling recently proposed ferromagnetic-like SU(4) states proposed to emerge in TBG at charge neutrality and other integer fillings [37,48]. Upon further increasing the interaction, a columnar valence bond solid (cVBS) insulator state appears, favored by the Hubbard-like interaction [63,64,73,74]. Importantly, the presence of the assisted-hopping term makes the QVH and IVC states accessible already for substantially smaller values of $U/W$, as compared to the case where there is only Hubbard repulsion. Therefore, the experimental observation of such quantum states in TBG at charge neutrality would provide strong evidence for the importance of nonlocal, topologically driven interactions in this system.

II. MODEL, SYMMETRY ANALYSIS, AND METHOD

Our lattice Hamiltonian $H$ for spinful fermions on the moiré superlattice consists of a noninteracting tight-binding term $H_0$ and an interaction term $H_C$. An important property of the narrow bands of TBG is their fragile topology, resulting in the phenomenon known as Wannier obstruction, which prevents the construction of localized Wannier orbitals that locally implement the symmetries of the system of coupled Dirac fermions (i.e., the so-called continuum model) [23]. There are essentially two ways to overcome the Wannier obstruction: (i) include additional remote bands (at the expense of adding more Wannier orbitals and the associated interactions) or (ii) implement one of the symmetries of the continuum model nonlocally (at the expense of adding longer-range hopping parameters). In case (ii), the Wannier orbitals, denoted by the operators $c_{lσ}$, live on the sites $l$ of the dual honeycomb moiré superlattice and are labeled by spin $σ = ↑, ↓$ and 2 orbital degrees of freedom, $l = 1, 2$ (roughly corresponding to the two valleys) [20,21]. In case (i), the Wannier orbitals
can live on the sites of the triangular moiré superlattice, and additional orbital quantum numbers are required.

Since we are interested in the strong-coupling regime, it is crucial to project the screened Coulomb repulsion onto the nonobstructed low-energy WSs. This was done in Ref. [37] for case (ii), which implemented the $C_2 T$ symmetry non-locally, where $C_2$ refers to twofold rotations with respect to the $z$ axis and $T$ to time reversal. This process was found to give rise to a nonlocal assisted-hopping interaction, besides the more standard Hubbard-like repulsion. More specifically, the interacting Hamiltonian in this case is given by the sum of two contributions [37],

$$H_O = U \sum_j (Q_j + aT_j - 4)^2.$$  \hspace{1cm} (1)

Here, $U$ sets the overall strength of the Coulomb interaction. The two terms in Eq. (1), illustrated in Fig. 1(a), consist of the cluster charge $Q_j = \sum_{i\in \sigma} (n_j / 3)$, with $n_j = \sum_{i=1}^{12} \sigma c_{j,i}^\dagger c_{j,i}$, and the cluster assisted hopping $T_j = \sum_{\sigma,\alpha} (ic_{j+1,1\sigma} c_{j,1\sigma} - ic_{j+1,2\alpha} c_{j,2\alpha} + \text{H.c.})$. The index $j = 1, \ldots, 6$ sums over all six sites of the elemental hexagon in the honeycomb lattice.

The cluster charge term $Q_j$ is analogous to the Hubbard on-site repulsion in the standard Hubbard model; it extends over the entire hexagon because of the screening length set by the separation between the gates in a TBG device and the overlap between WSs of neighboring sites. In particular, the Wannier wave functions are not peaked at the honeycomb sites but instead are extended and peaked at the centers of the three neighboring hexagons [20,21,23]. Therefore, one single WS overlaps spatially with other WSs on neighboring sites, leading to the cluster charging term $Q_j$. On the other hand, the origin of the assisted-hopping term $T$ is topological; i.e., it comes precisely from the fragile topology of TBG. This can be seen from the derivation of the coefficient $\alpha$, which controls the relative strength of the two interactions. It is the overlap of two neighboring WSs in a single hexagon, given as [37]

$$\alpha = -i \int \text{d}r w_{1,1}(r) w_{2,1}(r),$$  \hspace{1cm} (2)

where $w_{1,1}(r)$ is the wave function of the WS at site 1 of the hexagon with the valley index 1, and $w_{2,1}(r)$ is the WS at site 2 of the hexagon. Note that the integral is taken only inside the single hexagon. Although $\alpha$ is generally a complex number, its phase can always be removed by a gauge transformation. As argued in Ref. [37], the sizable value of $\alpha$ comes from the topological obstruction to the fully symmetric WSs. If the bands are topologically trivial, all the symmetries can be locally implemented for the WSs. As a consequence, the WSs are $C_2^\sigma$ symmetric.
and have the same parity. While two neighboring WSs overlap in two neighboring hexagons and sum to 0 because of the orthogonality, the two overlaps are equal since \( C_2 \) symmetry relates them together. Therefore, each one vanishes, leading to \( \alpha = 0 \). The sizable value of \( \alpha \) manifests the nontrivial topological properties of the narrow bands. In Ref. [37], \( \alpha \) was found to be 0.23 based on Koshino’s model, without including the lattice relaxation [75]. Since the relaxation will inevitably change \( \alpha \), we will not fix its value here but instead study the phase diagram for a wider range of \( \alpha \).

The nonlocal implementation of the \( C_2 T \) symmetry also results in many longer-range hopping parameters in \( H_0 \) [20]. Ideally, one would like to solve the model containing all of these tight-binding terms, but such a model would, in general, suffer from the sign problem and cannot be efficiently simulated with QMC, which has the advantage of being unbiased and applicable even for large interaction values. In contrast, the interaction term \( H_\Omega \) alone can be solved with QMC without the sign problem, despite the presence of the nonlocal interaction \( T_\Omega \) (see discussions in the Appendix A). Therefore, because we are interested in the strong-coupling regime, we opt to keep the full nontrivial interaction term and simplify the tight-binding Hamiltonian in order to circumvent the sign problem,

\[
H_0 = -t \sum_{\langle ij \rangle \sigma} (c_{i\sigma}^\dagger c_{j\sigma} + \text{H.c.}).
\]  

This simple nearest-neighbor band dispersion displays Dirac points at charge neutrality and can be simulated with sign-problem-free QMC at charge neutrality (four electrons per hexagon once averaging over the lattice), which we assume hereafter. Moreover, we set the hopping parameter \( t = 1 \) and use the bare bandwidth \( W = 6t \) as the energy unit in the remainder of the paper.

We emphasize that, in the strong-coupling regime, we expect that it is the nontrivial structure of the projected interactions that will determine the ground state and not the bare tight-binding dispersion. Below, we provide evidence that this is indeed the case. Thus, the crucial point is that the topologically nontrivial properties of the TBG band structure are already incorporated in the interacting part of our model, which inherits them from the projection of the screened Coulomb interaction on the nontrivial WSs.

An interesting feature of \( H_\Omega \) is its emergent SU(4) symmetry describing simultaneous rotations in spin and orbital spaces. To illustrate this feature, we introduce the spinor \( \psi_i = (c_{i\uparrow}, c_{i\downarrow}, c_{2i\uparrow}, c_{2i\downarrow})^T \) and rewrite the interactions as

\[
T_\Omega = i \sum_{i \in \Omega} \psi_i^\dagger T_0 \psi_i + \text{H.c.},
\]

with \( T_0 = \text{diag}(1, 1, -1, -1) \) denoting a diagonal matrix. Consider the unitary transformation

\[
\psi_{i, \alpha} \rightarrow U_i \psi_i \quad \text{and} \quad \psi_{j, \beta} \rightarrow T_0 U_i \psi_j,
\]

where \( U \) is an arbitrary \( 4 \times 4 \) unitary matrix and \( \mathcal{A}(\mathcal{B}) \) are the two sublattices of the honeycomb lattice. It is clear that both \( Q_\Omega \) and \( T_\Omega \) are invariant under this transformation. On the other hand, the kinetic term \( H_0 \) is not invariant under the transformation given by Eq. (6), thus leaving the whole Hamiltonian only \( U(1) \times SU(2) \times SU(2) \) symmetric, i.e., the valley \( U(1) \) symmetry and the two independent spin \( SU(2) \) rotations for the two valleys [23,43]. Thus, strictly speaking, the SU(4) symmetry is exact for \( H_\Omega \) but only approximate for \( H_0 \).

To solve the model \( H = H_0 + H_\Omega \) nonperturbatively, we employ large-scale projection QMC simulations [63,64]. This QMC approach, employed in several previous studies [63,64,73,76–79], provides results about the \( T = 0 \) ground state, the correlation functions (which are used to determine broken symmetries), and the electronic spectra (both single-particle and collective excitations). As explained above, despite the presence of the assisted-hopping interaction, the model at charge neutrality does not suffer from the sign problem (see Appendix A for details). Thus, it can be efficiently simulated by introducing an extended auxiliary bosonic field that dynamically couples to the electrons on a hexagon—in contrast to the standard Hubbard model, where the auxiliary field is local. Details about the projection QMC implementation, as well as comparison with results from exact diagonalization, are discussed in Appendixes A and B.

We also complemented the unbiased QMC simulations with self-consistent HF calculations, which are well suited for the weak-coupling regime and can be employed even when additional terms are included in \( H \) that introduce a sign problem for QMC. The HF approach is fully unrestricted in the sense that \( H_0 + H_\Omega \) is mean-field decoupled in all channels and free to acquire any value in site, spin, and valley space. Further technical details, including the resulting coupled set of (real space) self-consistency equations, can be found in Appendix C. In the regime of weak interactions, we find excellent agreement between the results obtained from HF and QMC. Importantly, in the same Appendix, we also extend the HF calculations to include longer-range hopping terms in \( H_0 \) and find that the results are similar. This result supports our aforementioned expectation that the nontrivial structure of the projected interactions, arising from the fragile topology of TBG, dominates the ground-state properties of the system, at least at charge neutrality.
III. QUANTUM VALLEY HALL PHASE, INTERVALLEY-COHERENT INSULATOR, AND VALENCE-BOND SOLID

The QMC-derived phase diagram for the ground states at charge neutrality is shown in Fig. 1(b) as a function of $U/W$ and $\alpha$. We emphasize that while $U$ gives the overall magnitude of the total interaction term, $\alpha$ is proportional to the relative strength between the assisted-hopping and cluster-charge terms. We find that three types of correlated insulating phases emerge in the phase diagram: the QVH phase, the IVC phase, and the cVBS.

The QVH phase is the ground state for small $U$ values and is characterized by a gap in the single-particle spectrum. This gap can be extracted from the imaginary-time decay of the Green’s function along a high-symmetry path of the Brillouin zone (BZ), $G(k, \tau) \sim e^{-\Delta_{sp}(k)\tau}$. Figure 2(a) shows the enhancement of the single-particle gap at the $K$ point of the BZ as a function of $U$ for a fixed $\alpha = 0.45$ (blue points). Together with Fig. 2(b), one sees that the gap opens at the entire BZ at infinitesimally small $U$. In many honeycomb lattice models, the Dirac cone at the $K$ point is protected by a symmetry, and the semimetal phase is robust against weak interactions [63,64,73,76]. In TBG, however, the relevant symmetry $C_2T$ cannot be implemented locally due to the topological Wannier obstruction, which opens up the possibility of very weak interactionsgapping out the Dirac cone.

In our QMC simulations, for any nonzero $\alpha$ that we investigated, a gap appears even for the smallest values of $U$ probed. This result suggests a weak-coupling origin of this phase. To verify it, we perform HF calculations on the same lattice model. The results, shown by the red points in Fig. 2(a), are in very good agreement with the QMC results. We also use HF to investigate the stability of the gap against changing the phase that appears in the assisted-hopping term $T_\bigtriangleup$ [37]. This phase can be gauged away, at the expense of introducing complex hopping terms in $H_0$, which introduce a sign problem to the QMC simulations. However, they do not affect the efficiency of the HF algorithm. As discussed in Appendix C, our analysis confirms that the onset of the QVH phase is robust and appears regardless of the phase of $T_\bigtriangleup$.

Importantly, we find that the gap completely disappears when $\alpha = 0$, in agreement with Ref. [64]. Combined with the fact that the gap opens for small interaction values when $\alpha \neq 0$, this suggests that the origin of the gap can be understood from a mean-field decoupling of the cross term $\sum_{Q} Q T_\bigtriangleup$ of the interaction in Eq. (1). This cross term can be rewritten as

$$\sum_{Q} Q T_\bigtriangleup = i \sum_{i,j=1}^{6} \sum_{m=1}^{2} (-1)^m (c_{i;l}^{\dagger} c_{j;i+1,m}^{\dagger} c_{j,m} c_{i,l} - \text{h.c.}),$$

(7)

where $l$ and $m$ are valley indices and the spin index is omitted for simplicity. The terms with $j = i-1$ and $j = i$ vanish after summing over different hexagons. In the weak-coupling limit, we can do a mean-field decoupling and use $\langle c_{i;l}^{\dagger} c_{j;i+1,m}^{\dagger} \rangle \propto \delta_{lm}$, due to the nearest-neighbor hopping term present in $H_0$. The cross term then becomes

$$\sum_{Q} Q T_\bigtriangleup \propto -i \sum_{i=1}^{6} \sum_{l=1}^{2} \sum_{l=1}^{2} (-1)^i \left( c_{i+l}^{\dagger} + c_{i+2,l}^{\dagger} + c_{i-2,l}^{\dagger} c_{i,l} - \text{h.c.} \right).$$

(8)

Thus, the cross term of the interaction naturally induces an imaginary hopping between next-nearest neighbor in the weak-coupling limit. As a consequence, the mean-field Hamiltonian becomes two copies (four, if we consider the spin degeneracy) of the Haldane model [80,81], leading to a Chern number of $\pm 1$ for the two different valleys. Hence we dub this phase QVH it is illustrated in the corresponding inset in Fig. 1(b). We verify that our
self-consistent HF calculation generates the same pattern of imaginary next-nearest-neighbor hopping.

One of the hallmarks of the Haldane model is the existence of gapless edge modes, despite the bulk being gapped. In the QVH phase, these edge states should be valley polarized. To probe them, we perform QMC simulations with open boundary conditions and extract the imaginary-time Green’s functions on the edge, \( G_{\text{edge}}(\tau) \sim e^{-\Delta_{\text{eff}} \tau} \). As shown in Fig. 2(c), in the regime of small \( U/W = 0.25 \), the Green’s function on the edge decays to a constant in the long imaginary-time limit, demonstrating the existence of a gapless edge mode in the QVH phase. To verify the existence of edge states, we also use HF to capture the topological nature of the QVH phase. In practice, we open the boundaries in the system and compute a self-consistent result with parameters as in Table I from Appendix C.

To show the real-space plot of the local density of states integrated over the histogram of the complex bond order parameter \( D_k \), at \( U/W \approx 5.3 \). The positions of the three peaks are those expected for a cVBS phase instead of a pVBS state.

![FIG. 3. In-gap local density of states in the QVH phase. We show the real-space plot of the local density of states integrated over \( 1.66 < E/W < 2.00 \), with \( U/W = 0.5 \). Here, \( r_{x,y} \) is the position of the lattice sites in units of the moiré lattice spacing, \( a_m \). The result is computed with open boundary conditions and parameters as in Table I from Appendix C.](image)

FIG. 4. IVC and cVBS insulating states. Correlation functions \( C_I(\Gamma) \) and \( C_B(\mathbf{K}) \), indicative of IVC and cVBS orders, respectively, as a function of \( U/W \) for (a) \( \alpha = 0.4 \) and (b) \( \alpha = 0.6 \). Linear system sizes are indicated in the legend. In both panels, the QVH-IVC transition, the IVC-cVBS transition, and the cVBS-IVC transition are all first order. The inset in panel (a) presents the histogram of the complex bond order parameter \( D_k \) at \( U/W \approx 5.3 \). The positions of the three peaks are those expected for a cVBS phase instead of a pVBS state.
\( \mathbf{k} = \mathbf{\Gamma} \) implies that the IVC order is ferromagnetic-like; i.e., it does not break translational symmetry. Such an on-site coupling between opposite valleys [see the corresponding inset in the phase diagram in Fig. 1(b)] breaks the valley \( U(1) \) symmetry and, hence, the \( SU(4) \) symmetry of the model. The fact that the \( SU(4) \) symmetry-breaking pattern is ferromagnetic-like is similar to recent analytical results [37,38], which focused, however, at integer fillings away from charge neutrality. We also note that our IVC state is different from that of Ref. [48] since our IVC phase does not have edge modes protected by a modified Kramers time-reversal symmetry, as is the case of the IVC state proposed in Ref. [48].

For larger values of \( U/W \) as shown in Fig. 4, the IVC order fades away, but the system remains insulating. The new state that emerges is the cVBS insulator, characterized by the appearance of strong nearest-neighbor bonds forming the pattern illustrated in the corresponding inset of Fig. 1(b). The onset of cVBS order is signaled by an enhancement of the bond-bond correlation function [63,64,73,74],\( C_B(\mathbf{k}) = (1/L^4) \sum_{i,j} e^{i \mathbf{k} \cdot (\mathbf{r}_i - \mathbf{r}_j)} \langle B_{i,\delta} B_{j,\delta} \rangle \), with bond operator \( B_{i,\delta} = \sum_{\sigma} c_{i,\delta \sigma}^\dagger c_{i,\delta \sigma} + \text{H.c.} \) and \( \delta \) denoting one of the three nearest-neighbor bond directions of the honeycomb lattice (\( \hat{e}_1, \hat{e}_2, \) and \( \hat{e}_3 \)). For this particular calculation, \( \hat{e}_1 \) was chosen.

As shown in the lower panels of Figs. 4(a) and 4(b), we find an enhanced \( C_B(\mathbf{k}) \) at momenta \( \mathbf{K} \) and \( \mathbf{K}' \), demonstrating that the bond-order pattern breaks translational symmetry. However, a peak of \( C_B(\mathbf{k}) \) at these momenta does not allow us to unambiguously identify the cVBS state, as the plaquette valence-bond solid (pVBS) also displays peaks at the same momenta [63,64,73]. To further distinguish the two types of VBS phases, we construct the complex order parameter \( D_K = (1/L^2) \sum_{i} \langle B_{i,\delta \sigma}^\dagger + \omega B_{i,\hat{e}_2} + \sigma^2 B_{i,\delta \sigma} \rangle e^{i \mathbf{k} \cdot \mathbf{r}_i} \) with \( \omega = e^{i 2\pi/3} \). The Monte Carlo histogram of \( D_K \) is different for the two VBS phases [73,74]: For the pVBS state, the angular distribution of \( D_K \) is peaked at arg(\( D_K \)) = \( \pi/3, \pi, 5\pi/3 \), whereas for the cVBS state, it is peaked at arg(\( D_K \)) = \( 0, 2\pi/3, 4\pi/3 \). Our results, shown in the inset of Fig. 4(a), clearly demonstrate that the cVBS order is realized in our phase diagram.

The phase boundaries in Fig. 1(b) are obtained by scanning the correlation functions \( C_\ell(\mathbf{\Gamma}) \) and \( C_B(\mathbf{K}) \) as a function of \( U/W \) for fixed values of \( \alpha \). Two of these scans are shown in Fig. 4, for \( \alpha = 0.4 \) [panel (a)] and \( \alpha = 0.6 \) [panel (b)]. It is clear that, as \( U/W \) increases, in both cases the ground state evolves from QVH to IVC to cVBS and then back to IVC. Furthermore, in the strong-coupling limit \( U/W \to \infty \), the IVC order \( C_\ell(\mathbf{k} = 0) \) is independent of \( \alpha \) and saturates at 0.5, consistent with our analytical calculation at the charge neutrality point (see Appendix D). The transitions between IVC to cVBS are first order, as signaled by the fact that as the system size \( L \) increases, the suppression of the IVC order becomes sharper [see, for instance, the region around \( U/W \sim 5 \) and \( U/W \sim 11 \) in panel (a)]. A similar sharp drop is also featured at the QVH-IVC transition [region around \( U/W \sim 2.5 \) in panel (a)], indicating that the QVH-IVC and IVC-cVBS transitions are all first order. It is interesting to note that, as \( \alpha \) increases, the values of \( U/W \) for which the IVC and cVBS phases emerge are strongly reduced.

We note that in the limit of vanishing bandwidth, our analyses in Appendixes A and D reveal that in this very-strong-coupling limit, the ground state of the system is in the IVC phase for the range of \( \alpha \) considered here.

**IV. DISCUSSION**

In this paper, we employed QMC simulations, which are exact and unbiased, to obtain the phase diagram of a lattice model of TBG at charge neutrality. Our main result is that even very small interaction values trigger a transition from the noninteracting Dirac semimetal phase to an insulating state. Upon increasing \( U \), the nature of the insulator changes from a nonsymmetry-breaking topological QVH phase to an on-site SU(4) symmetry-breaking IVC state, to a translational symmetry-breaking cVBS phase, and then finally back to a reentrant IVC state. This rich phase diagram is a consequence of the interplay between two different types of interaction terms: a cluster-charge repulsion \( Q_\circ \) and a nonlocal assisted-hopping interaction \( T_\circ \). The former is analogous to the standard Hubbard repulsion and, as such, is expected to promote either SU(4) antiferromagnetic order or valence-bond order in the strong-coupling regime. The latter, on the other hand, arises from the topological properties of the flat bands in TBG. When combined with \( Q_\circ \), it gives rise not only to SU(4) ferromagnetic-like order but also to correlated insulating phases with topological properties, such as the QVH phase.

While the precise value of \( U/W \) in TBG is not known, a widely used estimate is that this ratio is of order 1 [37]. Referring to our phase diagram in Fig. 1(b), this means that certainly the QVH phase and possibly the IVC phase can be realized at charge neutrality, provided that \( \alpha \) is not too small. While some experimental probes report a gap at charge neutrality (Refs. [10,11]), additional experiments are needed to establish its ubiquity among different devices and the nature of the insulating state. The main manifestation of the QVH phase would be the appearance of gapless edge states, whereas in the case of the IVC state, it would be the emergence of a \( \mathbf{k} = 0 \) order with on-site coupling between the two different valleys.

A number of recent insightful Hartree-Fock studies have also reported several unusual ordered states at charge neutrality [44,48,49,71,72]. In their approach, starting from the Bistritzer-MacDonald (BM) continuum wave functions, the Coulomb interactions are projected by use of the continuum model and typically include several remote bands. As usual, HF studies can depend crucially on the
restrictions imposed in the search for ordered states, which may explain the rich variety of proposed spontaneously symmetry-broken phases identified from the continuum approach, including a semimetal phase, quantum Hall insulator, valley-Hall, and spin- and valley-polarized phases. Recently, Ref. [48], allowing for coherence between the two valleys, argued that the resulting insulating IVC phase is the ground state at charge neutrality for a broad parameter range. As discussed in the Introduction of this paper, we have presented a complementary approach; starting from the strongly interacting limit, we have applied the topologically nontrivial projected Coulomb interaction and utilized fully unrestricted and unbiased numerical methods able to handle cases where the scale of interactions exceeds the kinetic bandwidth, to identify the ordered states at charge neutrality. In qualitative agreement with some earlier studies, we locate an IVC phase from this strong-coupling approach but additionally identify both the QVH and a translationally symmetry-breaking cVBS phase. While HF calculations with the Bloch states usually produce homogeneous phases without breaking the translation symmetry, more recent density matrix renormalization group (DMRG) calculations with hybrid WSs have identified the stripe phase as a strong candidate for a ground state in a toy BM model without spin and valley degrees of freedom [54,66]. In agreement with the DMRG calculations, our QMC study found that the increasing kinetic terms drive the system from the IVC phase in the strong coupling limit into the cVBS phase in a more intermediate coupling regime.

In a more general context beyond TBG, our work offers a promising route to realize correlation-driven topological phases. As explained above, the topological QVH insulating state appears due to the cross term in the interaction Hamiltonian that contains both $Q_0$ and $T_0$. While repulsive interactions similar to the charge-cluster term are generally expected to appear in any correlated electronic system, an interesting question is about the necessary conditions for the emergence of an interaction similar to the assisted hopping. In our case, it arises from the projection of the standard Coulomb repulsion on WSs that suffer from topological obstruction. The latter, in turn, is a manifestation of the phenomenon of fragile topology [83]. Thus, interacting systems with fragile topology may offer an appealing route to search for interaction-driven topological states. While here the Wannier obstruction arising from the fragile topology is circumvented by implementing the $C_2T$ symmetry of the continuous model nonlocally, another route is to include the remote bands, separated from the narrow bands of TBG by a sizable gap. While we expect the ground state to be the same regardless of how the Wannier obstruction is avoided, it is an interesting open question to establish the strong-coupling phase diagram of TBG starting from a model containing both the narrow and remote bands.

ACKNOWLEDGMENTS

We thank Eslam Khalaf, Ashvin Vishwanath, and Yi Zhang for insightful conversations on the subject, especially on the nature of the IVC phase. We also thank Oskar Vafek for valuable suggestions and for pointing out a missing factor in the IVC correlation function. Y. D. L. and Z. Y. APPENDIX A: PROJECTION QMC METHOD

1. Construction

Since we are interested in the ground-state properties of the system, the projection QMC (PQMC) is the method of choice [76,79,84]. In PQMC, one can obtain a ground-state wave function $|\Psi_0\rangle$ from projecting a trial wave function $|\Psi_T\rangle$ along the imaginary axis $|\Psi_0\rangle = \lim_{\Theta \to -\infty} e^{-(\Theta/2)\hat{H}}|\Psi_T\rangle$; then, the observable can be calculated as

$$\langle \hat{O} \rangle = \frac{\langle \Psi_0 | \hat{O} | \Psi_0 \rangle}{\langle \Psi_0 | \Psi_0 \rangle} = \lim_{\Theta \to -\infty} \frac{\langle \Psi_T | e^{-\Theta\hat{H}} \hat{O} e^{-\Theta\hat{H}} | \Psi_T \rangle}{\langle \Psi_T | e^{-\Theta\hat{H}} | \Psi_T \rangle} \quad (A1)$$

To evaluate overlaps in the above equation, we perform Trotter decomposition to discretize $\Theta$ into $L_\tau$ slices ($\Theta = L_\tau \Delta \tau$). Each slice $\Delta \tau$ is small, and the systematic error is $O(\Delta \tau^2)$. After the Trotter decomposition, we have
Every hexagon contains six sites, as shown in the figure below, so our $V$ matrix is a block matrix; every block contributes a $6 \times 6$ matrix,

$$\begin{pmatrix}
\frac{1}{2} & i\alpha & -i\alpha & 0 & 0 & 0 \\
i\alpha & \frac{1}{2} & 0 & i\alpha & 0 & 0 \\
i\alpha & 0 & \frac{1}{2} & 0 & -i\alpha & 0 \\
0 & -i\alpha & 0 & \frac{1}{2} & 0 & i\alpha \\
0 & 0 & i\alpha & 0 & \frac{1}{2} & -i\alpha \\
0 & 0 & 0 & -i\alpha & i\alpha & \frac{1}{2}
\end{pmatrix}$$

The configurational space $\{s_\Omega(i, \tau)\}$ with size $L \times L \times \Theta$ is the space in which the physical observables in Eq. (A1) are computed with ensemble average. We choose the projection length $\Theta = 2L/t$ and discretize it with a step $\Delta \tau = 0.1/t$. The spatial system sizes are $L = 6, 9, 12, 15$.

The Monte Carlo sampling of auxiliary fields is further performed based on the weight defined in the sum of Eq. (A4). The measurements are performed near $\tau = \Theta/2$.

Single-particle observables are measured by the Green’s function directly, and many-body correlation functions are measured by the products of single-particle Green’s functions based on their corresponding form after Wick decomposition. The equal-time Green’s function is calculated as

$$G(\tau, \tau) = 1 - R(\tau)|L(\tau)R(\tau)|^{-1}L(\tau),$$

with $R(\tau) = B(\tau, 0)P, L(\tau) = P^\dagger B(\Theta, \tau)$.

2. Absence of sign problem

At the charge neutrality point, the model is sign-problem-free, as can be seen from the following analysis. Define $W_{s.l.s}$ as the updated weight of one fixed auxiliary field at the $i$th hexagon, where $l = 1, 2$ is a valley or orbital index and $\sigma = \uparrow, \downarrow$ is a spin index. From the symmetry of the Hamiltonian, $W_{s,l,s} = W_{1,s,l,s}$. Since the model is particle-hole symmetric at charge neutrality, one can perform a particle-hole transformation (PHS) only for the valley $l = 2$. Then, one can focus on a fixed auxiliary field and focus only on one spin flavor, such as spin up. Equation (A3) in the main text can then be abbreviated as Eqs. (A7) and (A8). Applying PHS for valley 2 and using the relation Eq. (A9), we find that Eq. (A8) becomes Eq. (A10),

For $l = 1$,

$$\exp \left( i\alpha \eta(S_i) \frac{1}{2} \sum_{p=1}^{6} \left( i\epsilon^\dagger_{p+1,1,\uparrow} c_{p,1,\uparrow} - i\epsilon^\dagger_{p,1,\uparrow} c_{p+1,1,\uparrow} \right) + \frac{1}{3} \sum_{p=1}^{6} \left( c^\dagger_{p,1,\uparrow} c_{p,1,\uparrow} - \frac{1}{2} \right) \right),$$

For $l = 2$,

$$\exp \left( i\alpha \eta(S_i) \frac{1}{2} \sum_{p=1}^{6} \left( -i\epsilon^\dagger_{p+1,2,\uparrow} c_{p,2,\uparrow} + i\epsilon^\dagger_{p,2,\uparrow} c_{p+1,2,\uparrow} \right) + \frac{1}{3} \sum_{p=1}^{6} \left( c^\dagger_{p,2,\uparrow} c_{p,2,\uparrow} - \frac{1}{2} \right) \right),$$

$$-i\epsilon^\dagger_{p+1,2,\uparrow} c_{p,2,\uparrow} + i\epsilon^\dagger_{p,2,\uparrow} c_{p+1,2,\uparrow} \rightarrow i\epsilon^\dagger_{p+1,1,\uparrow} c_{p,1,\uparrow} - i\epsilon^\dagger_{p,1,\uparrow} c_{p+1,1,\uparrow}.$$

011014-9
For \( l = 2\text{PHS}, \)
\[
\exp \left( i \alpha \eta (S_i) \left[ \sum_{p=1}^{6} \left( ic_{p+1,2,\uparrow} c_{p,2,\uparrow} - ic_{p+1,2,\downarrow} c_{p,2,\downarrow} \right) + \frac{1}{3} \sum_{p=1}^{6} \left( \frac{1}{2} - c_{p+1,2,\uparrow} c_{p,2,\downarrow} \right) \right] \right), \tag{A10}
\]

For \( l = 1, \)
\[
e^{-i \alpha \eta (S_i) A} \to e^{-i \alpha \eta (S_i) B} e^{i \alpha \eta (S_i) A},
\]

For \( l = 2\text{PHS}, \)
\[
e^{-i \alpha \eta (S_i) B} e^{i \alpha \eta (S_i) A} \to e^{-i \alpha \eta (S_i) B} e^{-i \alpha \eta (S_i) A}. \tag{A11}
\]

Let us define the matrices \( \mathbf{A} = \frac{1}{2} \sum_{p=1}^{6} \left( c_{p+1,2,\uparrow} c_{p,2,\uparrow} - \frac{1}{2} \right) \) and \( i \mathbf{B} = \sum_{p=1}^{6} \left( ic_{p+1,1,\uparrow} c_{p,1,\uparrow} - ic_{p+1,1,\downarrow} c_{p,1,\downarrow} \right) \) or, equivalently, \( \mathbf{B} = \frac{1}{2} \sum_{p=1}^{6} \left( c_{p+1,1,\uparrow} c_{p,1,\uparrow} - c_{p+1,1,\downarrow} c_{p,1,\downarrow} \right) \). The matrices \( \mathbf{A} \) and \( \mathbf{B} \) are real matrices. Then, due to the fact that the matrix \( \mathbf{A} \) is a diagonal matrix and \( \mathbf{A}_{ii} = \mathbf{A}_{jj} \), Eqs. (A7) and (A10) can be written as Eq. (A11).

Because of the relations above, the total weight of the model is \( \sum_{s_i} W_{1,s_i} \times W_{2,s_i} \times W_{3,s_i} \times W_{4,s_i} = \sum_{s_i} (W_{1,s_i} W_{2,s_i})^2 \), which is a real positive number. This result implies that the QMC simulations are sign-problem-free.

### 3. Strong-coupling limit

The PQMC simulations can also be applied at the strong-coupling limit, where the Hamiltonian only contains the interaction part \( H_{\text{IC}} \). We have performed the corresponding simulations and found, as a function of \( \alpha \), that the system is always in the IVC phase since the corresponding correlation function \( C_l(\Gamma) \) is close to the saturation value of 0.5. At the same time, the correlation function of the cVBS phase, \( C_B(K) \), approaches zero as the system size increases. The results are shown in Fig. 5. This case is consistent with the theoretical analysis in this limit discussed in Appendix D.

### APPENDIX B: BENCHMARK WITH EXACT DIAGONALIZATION

We employ Lanczos exact diagonalization (ED) to benchmark the PQMC results, shown in Fig. 6. The system contains \( 2 \times 2 \) unit cells of the honeycomb lattice with periodic boundary conditions (16 electrons in total). We make use of symmetries, such as the valley \( U(1) \) symmetry and the total \( S_z \) conservation for each valley, to reduce the computational cost of the ED. The ground state lies in the subspace with \( N_{\uparrow} = 4, N_{\downarrow} = 4 \) in both valleys, where \( N_{\uparrow}(N_{\downarrow}) \) is the number of electrons with spin up (down) in each valley. The dimension of the ground-state subspace is about \( 24 \times 10^6 \). In the PQMC simulations, we choose the linear system size \( L = 2 \) and the projection length \( \Theta = 100 / t \) with Trotter slice \( \Delta t = 0.0005 / t \). We compare the ground-state expectation values of \( \langle H_0 \rangle \) and of the double occupation as a function of \( U / t \) at \( \alpha = 0.3 \), which are shown below. The results of both methods agree very well.

### APPENDIX C: HARTREE-FOCK METHOD

To solve the TBG model within the Hartree-Fock approach, we write the Hamiltonian in Eq. (1) of the main text as
\[
H_0 = U \sum_{\circ} \langle Q_\circ + \alpha T_\circ \rangle (Q_\circ + \alpha T_\circ) \tag{C1}
\]
where primes indicate independent index summations. The direct terms immediately give
\[
H^H_0 = 2U \sum_{\circ} \langle Q_\circ + \alpha T_\circ \rangle (Q_\circ + \alpha T_\circ) \tag{C2}
\]

![FIG. 5. \( C_l(\Gamma) \) and \( C_B(K) \) as a function of \( \alpha \) at the strong-coupling limit. We perform the QMC simulation with projection length \( \Theta = 200L \), interval of time slice \( \Delta t = 0.1 \), and spatial system sizes \( L = 9, 12 \), and by setting \( U = 1 \) as a dimensionless constant. The corresponding correlation function \( C_l(\Gamma) \) of IVC is close to the saturation value of 0.5, and the correlation function \( C_B(K) \) of the cVBS is close to 0, which means the cVBS disappears at the strong-coupling limit.](011014-10)

![FIG. 6. (a) Kinetic energy and (b) double occupancy as a function of \( U/W \) for \( \alpha = 0.3 \). Red circles and blue squares with error bars are obtained from ED and QMC, respectively.](011014-10)
The exchange terms are given in Eq. (C3), where \( \sum_{\sigma} = (\sum_{l',\sigma} \sum_{l,\sigma'} \sum_{i=1}^{6} |c_{i,l \sigma} c_{i,l' \sigma'}|^2 + \text{H.c.}) \). Manipulating and collecting terms in Eqs. (C2) and (C3) yields the Hartree-Fock Hamiltonian Eq. (C3).

\[
H^\alpha_F = -U \sum_\alpha \sum_{l',l} \left[ \frac{1}{9} \left| (c^{\dagger}_{l',l \sigma} c_{l,l' \sigma})^2 + \text{H.c.} \right| + \frac{\alpha i}{3} \left[ \left| (-)^{l'+1} (c^{\dagger}_{l',l \sigma} c_{l,l' \sigma})^2 + \text{H.c.} \right| + \left| (-)^{l} (c^{\dagger}_{l',l \sigma} c_{l,l' \sigma})^2 + \text{H.c.} \right| \right] 
+ \alpha^2 l^2 \left[ \left| (-)^{l'+1} (c^{\dagger}_{l',l \sigma} c_{l,l' \sigma})^2 + \text{H.c.} \right| + \left| (-)^{l} (c^{\dagger}_{l',l \sigma} c_{l,l' \sigma})^2 + \text{H.c.} \right| \right] 
- \left| (-)^{l'+1} (c^{\dagger}_{l',l \sigma} c_{l,l' \sigma})^2 + \text{H.c.} \right| \right] 
\]

\[
H^{\text{HF}} = 2U \sum_\alpha \left\{ \tilde{\alpha}_\alpha (Q_{\alpha} + aT_{\alpha}) - \sum_{n,m} \left[ \sum_{-n,m} \left( \alpha_{n/(l')} \alpha_{m(l+1)} \right) ||c_{i,l \sigma} c_{i,l' \sigma}\right] \right\}. \tag{C3}
\]

Here, \( n, m = \{-1, 0, 1\} \), and we have defined

\[
\tilde{\alpha}_\alpha = \langle Q_{\alpha} + aT_{\alpha} \rangle, \\
\alpha(l) = \begin{pmatrix} \alpha_{-1} \\ \alpha_0 \\ \alpha_1 \end{pmatrix} = \begin{pmatrix} (-1)^l i \alpha \\ 1/3 \\ (-1)^{l+1} i \alpha \end{pmatrix}.
\]

We solve the full Hartree-Fock Hamiltonian \( H = H_0 + H^{\text{HF}} \) self-consistently using

\[
\langle c_{k \lambda}^{\dagger} c_{\lambda} \rangle = \sum_{\nu = 1}^{N} U^{\dagger}_{\epsilon \nu} U_{\nu \lambda} \langle \gamma^{\dagger}_{\nu} \gamma_{\lambda} \rangle = \sum_{\epsilon} U^{\dagger}_{\epsilon \nu} U_{\lambda \epsilon} f(E_{\epsilon}, \mu), \tag{C4}
\]

where \( \nu, \lambda = \{il\sigma\} \), \( U \) is the unitary transformation diagonalizing \( H \), \( \gamma \)'s are the eigenvectors, and \( f(E_{\epsilon}, \mu) \) is the Fermi-Dirac distribution of the excitation energies \( E_{\epsilon} \). We explicitly write the dependence on the chemical potential, \( \mu \), as we iterate this value to fulfill \( N^{-1} \sum_{\epsilon} f(E_{\epsilon}, \mu) = \nu \), where \( \nu \) is the filling.

We compute results at charge neutrality (\( \nu = 0.5 \)) with a total of 600 lattice sites and periodic boundary conditions. The calculations are fully unrestricted; thus, we iterate all \( (4 \times 600)^2 \) mean fields and define the convergence by the condition that \( \sum |\Delta E_{\epsilon}| < N \times 10^{-10} \) where \( \Delta E_{\epsilon} \) is the change of the excitation energies from one iteration to the next, and \( N \) is the total number of states \( (4 \times 600) \). In Table I, we present an example of the HF calculations, displaying results for \( t = 1 \), \( \alpha = 0.45 \), and \( U/W = 0.5 \). We set the temperature \( T = 2.5 \times 10^{-5} \) in all computations. The values in the table are the renormalized mean fields. It is evident that all hoppings within each hexagon are renormalized due to the interactions. The simple hopping renormalizations, however, do not open a gap in the Dirac cones. The gap is generated directly by the mean fields \( \langle c_{i,1,\sigma}^{\dagger} c_{i,2,\sigma} \rangle = -\langle c_{i,2,\sigma}^{\dagger} c_{i,1,\sigma} \rangle = 0.0914 \), which explicitly display a spin-degenerate QVH phase, as illustrated in Fig. 1(b) of the main text.

In Fig. 7(a), we show the single-particle gap in the QVH phase with \( \alpha = 0.45 \) for several interaction strengths. Figure 7(b) displays the corresponding band structures. The Dirac cone at \( K \) in the bare bands is immediately gapped out when including interactions. The renormalization initially flattens the bands with a significant gap at all high-symmetry points. As \( U \) increases, the valence band gradually develops a peak at \( \Gamma \) while it is pushed down correspondingly at \( K \). This behavior results in a gradual shift of the maximal gap value from \( \Gamma \) to \( K \).

**FIG. 7.** QVH insulator and band structures. (a) Single-particle gap \( \Delta/W \) along the high-symmetry path of the BZ with \( \alpha = 0.45 \) and various interaction strengths. The Dirac cones are gaped at infinitely small \( U \), and the system enters the QVH state. The maximal gap value gradually shifts from \( \Gamma \) to \( K \). (b) Band structures at various interaction strengths with \( \alpha = 0.45 \). The top-left plot displays the bare kinetic bands in the absence of any interactions. The Dirac cone at \( K \) is evident and confirms the semimetallic phase of the bare bands. The remaining three plots of (b) present the renormalized band structures with increasing \( U \). The two bands flatten for small \( U \) and gradually develop a peak at \( \Gamma \). All bands are fourfold degenerate, as the QVH phase does not break the approximate \( SU(4) \) symmetry.
QVH phase is very robust to the addition of long-range hoppings in $H_0$. The resulting bands with and without long-range hopping can be seen in Fig. 8.

Finally, we present results obtained by implementing the interaction terms found in Ref. [37]. As mentioned in the discussion section of the main text, we are able to solve this model within the HF approach as it does not suffer from sign problems. The assisted hopping reads

$$T_\circ = \sum_{i=1}^{6} \sum_{l,\sigma} (-)^{i-1} (c_{i\alpha}^\dagger c_{i+1\alpha} + \text{H.c.}).$$

The other terms, $Q_\circ$ and $H_0$, remain unchanged. To reach this expression for $T_\circ$, we have performed the following gauge transformation,

$$c_{i\alpha} \rightarrow e^{i\theta_{i}/2} c_{i\alpha} \quad i \text{ odd},$$
$$c_{i\alpha} \rightarrow e^{-i\theta_{i}/2} c_{i\alpha} \quad i \text{ even}.$$  \hspace{1cm} (C6)

The transformation introduces phases in $H_0$, effectively causing $t$ to become complex. We set the phases according to Ref. [37], that is, $\theta_1 = -\theta_2 = 0.743\pi$. The renormalized mean fields are presented in Table II, where we have performed the inverse gauge transformation for direct comparison with Table I. Input parameters are the same as those used to generate Table I. The result is consistent with the values presented in Table I and clearly also features a QVH phase.

APPENDIX D: STRONG-COUPLING LIMIT AT THE CHARGE NEUTRALITY POINT

For the system at the charge neutrality point, each unit cell contains four fermions on average. Following the

**TABLE I.** Mean-field renormalization with $U/W = 0.50$ and $\alpha = 0.45$. The input on $[c_{i\alpha}^\dagger, c_{j\beta}]$ represents the renormalized mean-field parameter $\langle c_{i\alpha}^\dagger c_{j\beta} \rangle$. The result is homogeneous and spin degenerate; hence, the listed values contain information about all sites and flavors. Note that interactions have generated neither spin nor valley mixing. We have subtracted the bare band contributions evaluated at $\nu = 0.5$ and ignored all mean fields with $|\langle |MF|_{\text{max}}/|MF| \rangle| > 100$.

</table>
method applied in Ref. [37], the ground state $|\Psi_{gs}\rangle$ of the interaction $H_0$ should be annihilated by the assisted-hopping operator $T_0$ for any hexagon. The most general form of the wave function is

$$|\Psi_{gs}\rangle = \prod_i \sum_{a\beta} U_{1a} U_{2a} \psi_i^{a\uparrow} \psi_i^{a\downarrow} |\varnothing\rangle,$$  

for any hexagon. The most general form of the wave function is

where $\psi_i^{a\uparrow} = (c_{i,1,\uparrow}, c_{i,1,\downarrow}, (-)^{i(i)} c_{i,2,\uparrow}, (-)^{i(i)} c_{i,2,\downarrow})^T$, and $U_{a\beta}$ is an arbitrary $4 \times 4$ matrix.

### 1. $H_0 = 0$

In the case of zero kinetic energy, the manifold of the ground states is described by Eq. (D1) and thus can be compared with the numerical results produced by QMC. For this purpose, we consider the correlation function:

$$I_{i\uparrow} = (c_{i,1,\uparrow}^{\dagger} c_{i,2,\uparrow} + \text{H.c.}),$$

$$I_{i\downarrow} = (c_{i,1,\downarrow}^{\dagger} c_{i,2,\downarrow} + \text{H.c.}),$$

which leads to

$$C_i^{AA} = \frac{1}{L^4} \sum_{i,j \in A} \langle \langle I_{i\uparrow} + I_{i\downarrow} \rangle \rangle 
= \frac{1}{L^4} \sum_{i,j \in A} \langle \langle I_{i\uparrow} I_{i\uparrow} \rangle \rangle 
= 2 \times (|U_{11}|^2 |U_{13}|^2 + |U_{21}|^2 |U_{23}|^2 + |U_{12}|^2 |U_{14}|^2 
+ |U_{22}|^2 |U_{24}|^2) = \frac{1}{2}.$$ 

Note here that $\langle \langle \cdots \rangle \rangle$ is the average over all possible $4 \times 4$ unitary matrices, and therefore, $U_{ij}^* U_{kl} = \frac{1}{4} \delta_{ik} \delta_{jl}$. Similarly, we can obtain $C_i^{AB} = C_i^{BA} = -C_i^{AA} = \frac{1}{2}$.

### 2. Strong-coupling limit

In this subsection, we assume that $H_0$ is finite but small compared with $H_0$. Since the kinetic terms break $SU(4)$ symmetry, the ground-state manifold shrinks and becomes a subset of the manifold described in Eq. (D1). Our purpose here is to identify the new manifold of the ground states and show that it is independent of the exact form of kinetic terms as along as it breaks the $SU(4)$ symmetry described in the main text.

For the convenience of calculation, we write Eq. (D1) in the following form:

$$|\Psi_{gs}\rangle = \prod_i (\alpha_i c_{i,1,\uparrow}^{\dagger} + (-)^{i(i)} \alpha_2 c_{i,2,\uparrow}^{\dagger})$$

$$\times (\gamma (\alpha_2 c_{i,1,\downarrow}^{\dagger} - (-)^{i(i)} \alpha_1 c_{i,2,\downarrow}^{\dagger}) + \beta_1 c_{i,1,-\downarrow}^{\dagger}$$

$$+ (-)^{i(i)} \beta_2 c_{i,2,-\downarrow}^{\dagger}) |\varnothing\rangle,$$  

where $(i(i) = 0$ and 1 if the site $i$ is on sublattice $A$ and $B$, respectively. Here, $\hat{n}$ and $\hat{m}$ are two arbitrary spin quantization directions, and $\alpha_1, \alpha_2, \beta_1, \beta_2$ are four complex variables that satisfy $|\alpha_1|^2 + |\alpha_2|^2 = |\gamma|^2 + |\beta_1|^2 + |\beta_2|^2 = 1$.

Furthermore, consider the hopping between two sites. We show next that the energy is minimized when $|\alpha_1| = |\alpha_2| = 1/\sqrt{2}, \gamma = 0$, and $|\beta_1| = |\beta_2| = 1/\sqrt{2}$.

Applying the second-order perturbation theory, the correction to the energy of the ground state is found to be

$$\delta E = \sum_n \frac{|\langle n| H_0 |\Psi_{gs}\rangle|^2}{E_0 - E_n},$$

where $n$ sums over all the excited states. Since it is almost impossible to obtain the exact spectrum of the excited states, we will maximize the term $\sum_n |\langle n| H_0 |\Psi_{gs}\rangle|^2$ instead of $\delta E$. Furthermore, note that $\langle GS| H_0 |GS\rangle = 0$, and write $H_0 = \sum_{i,j} K(i,j)$, where $i$ and $j$ refer to the honeycomb lattice site; we obtain

$$\sum_n |\langle n| H_0 |\Psi_{gs}\rangle|^2 = \|H_0 |\Psi_{gs}\rangle\|^2 = \sum_{i,j} |K(i,j)|^2 |\Psi_{gs}\rangle|^2.$$

For notational convenience, it is worth introducing $f_{i,a} = \sum_{\alpha} \psi_i^{a\alpha} U_{a\alpha}$, where $U$ is a unitary $4 \times 4$ matrix, and the ground state is given by

$$|\Psi_{gs}\rangle = \prod_i \prod_{a=1}^2 f_{i,1}^{a\uparrow} f_{i,2}^{a\downarrow} |\varnothing\rangle.$$ 

From Eq. (D4), it is obvious that

$$U_{1a} = (\alpha_1, 0, \alpha_2, 0) \quad U_{2a} = (\gamma \alpha_2, \beta_1, -\gamma \alpha_1, \beta_2).$$

We introduce the diagonal matrix

$$T = \text{diag} (t, t, (-)^{(i)(i)} + (j)(j) T^*, (-)^{(i)(i)} + (j)(j) T^*),$$

where $t$ is the hopping constant from site $j$ to site $i$ for valley 1. The kinetic terms can be written as

$$K(i,j) = \psi_i^{a\alpha} T_{a\beta} \psi_j^{b\beta} = f_{i,1}^{a\uparrow} (U^T T U)_{a\beta} f_{j, \beta}.$$

Now, it is easy to derive
\[ \| K(i, j) | \Psi_{GS} \| \|^2 = \sum_{i,j} \sum_{a=3}^{4} \sum_{b=1}^{3} T_{ii} T_{jj} U_{ia} U_{ib} U_{ja} U_{jb} \]
\[ = \sum_{i,j} T_{ii} T_{jj} \left( \delta_{ij} - \sum_{a=1}^{3} U_{ia} U_{ja} \right) U_{ib} U_{jb} \]
\[ = \sum_{i} \sum_{b=1}^{3} | U_{ib} |^2 - \sum_{ij} \sum_{ab=1}^{2} T_{ii} T_{jj} U_{ia} U_{ib} U_{ja} U_{jb} \]
\[ = 8 | \theta |^2 - \sum_{ij} \sum_{ab=1}^{2} T_{ii} T_{jj} U_{ia} U_{ib} U_{ja} U_{jb}. \quad (D5) \]

Since the first term is independent of the form of the ground state, we need to minimize the last term. Notice the T matrix can be written as

\[ T = t_0 I_{4 \times 4} + t_1 \text{diag}(1, 1, -1, -1), \]
and \( t_{0,1} = \frac{1}{2} (t \pm (-1)^{x+y} t^*) \), which leads to \( t_0 \hat{t}_1 \), is a pure imaginary number. Thus, we find

\[ \| K(i, j) | \Psi_{GS} \| \|^2 = 8 | \theta |^2 - 8 | t_0 |^2 - | t_1 |^2 \sum_{ab} | M_{ab} |^2. \quad (D6) \]

where \( M \) is a 2 × 2 matrix given by

\[ M = \begin{pmatrix} | \alpha_1 |^2 - | \alpha_2 |^2 & 2 \gamma i \alpha_1 \alpha_2^* \\ 2 \gamma \alpha_1 \alpha_2 & -| \beta_1 |^2 - | \beta_2 |^2 \end{pmatrix}. \]

Clearly, the energy due to the second-order perturbation is minimized when \( | \alpha_1 | = | \alpha_2 | = 1/\sqrt{2}, \gamma = 0 \), and \( | \beta_1 | = | \beta_2 | = 1/\sqrt{2}. \)

It is worth emphasizing that this result is independent of the exact form of the kinetic terms. As long as the hoppings break the \( SU(4) \) symmetry, the second-order perturbation always leads to the same manifold of the ground states.

As a consequence, the ground state is an equal mixture of two valleys. It is easy to obtain

\[ \langle c_{i,1,\uparrow}^† c_{i,2,\uparrow} \rangle = (-)^{(i)(j)} \alpha_1^* \alpha_2, \]
\[ \langle c_{i,1,\downarrow}^† c_{i,2,\downarrow} \rangle = 0, \]
\[ \langle c_{i,1,\uparrow}^† c_{i,2,\downarrow} \rangle = (-)^{(i)(j)} \beta_1^* \beta_2. \quad (D7) \]

Suppose that \( \hat{n} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta) \) and \( \hat{m} = (\sin \theta' \cos \phi', \sin \theta' \sin \phi', \cos \theta') \). We obtain

\[ I_{i,\uparrow} = \langle c_{i,1,\uparrow}^† c_{i,2,\uparrow} + \text{H.c.} \rangle = (-)^{(i)} \left( \cos \frac{\theta}{2} \cos \frac{\theta'}{2} \alpha_1^* \alpha_2 + \sin \frac{\theta}{2} \sin \frac{\theta'}{2} e^{i(\phi-\phi')} \beta_1^* \beta_2 + \text{c.c.} \right). \quad (D8) \]
\[ I_{i,\downarrow} = \langle c_{i,1,\downarrow}^† c_{i,2,\downarrow} + \text{H.c.} \rangle = (-)^{(i)} \left( \cos \frac{\theta}{2} \cos \frac{\theta'}{2} \beta_1^* \beta_2 - \sin \frac{\theta}{2} \sin \frac{\theta'}{2} e^{i(\phi-\phi')} \alpha_1^* \alpha_2 + \text{c.c.} \right). \quad (D9) \]

As a consequence, when averaging over all the possible configurations of the ground states, we obtain

\[ C_{i,A}^{A,A} = \frac{1}{L^2} \sum_{i,j \in A} \langle (I_{i,\uparrow} + I_{i,\downarrow})(I_{j,\uparrow} + I_{j,\downarrow}) \rangle = \frac{1}{L^2} \sum_{i,j \in A} \langle (I_{i,\uparrow} I_{j,\downarrow} + I_{i,\downarrow} I_{j,\uparrow}) \rangle \]
\[ = 2 \left( \langle \cos^2 \frac{\theta}{2} \cos^2 \frac{\theta'}{2} \rangle | \alpha_1 |^2 | \alpha_2 |^2 + | \beta_1 |^2 | \beta_2 |^2 \rangle + \langle \sin^2 \frac{\theta}{2} \sin^2 \frac{\theta'}{2} \rangle | \alpha_1 |^2 | \alpha_2 |^2 + | \beta_1 |^2 | \beta_2 |^2 \rangle \right). \quad (D10) \]
