ABSTRACT

In early-type galaxies, externally accreted gas is thought to be the main source of gas replenishment at late times. We use MUSE integral field spectroscopy data to study the active S0 galaxy NGC 5077, which is known to have disturbed dynamics that are indicative of a past external interaction. We confirm the presence of a stellar kinematically distinct core with a diameter of 2.8 kpc that is counter-rotating with respect to the main stellar body of the galaxy. We find that the counter-rotating core consists of an old stellar population that is not significantly different from the rest of the galaxy. The ionised gas is strongly warped and extends out to 6.5 kpc in the polar direction and in a filamentary structure. The gas dynamics is complex, with significant changes in the position angle as a function of radius. The ionised gas line ratios are consistent with LINER excitation by the active galactic nucleus, both in the nucleus and at kiloparsec scales. We discover a nuclear outflow with projected velocity $V \sim 400 \text{ km s}^{-1}$, consistent with a hollow outflow cone intersecting the plane of the sky. The properties of the misaligned gas match predictions from numerical simulations of misaligned gas infall after a gas-rich merger. The warp and change in the gas orientation as a function of radius are consistent with gas relaxation due to stellar torques; these are stronger at small radii where the gas aligns faster than in the outer regions, driving gas to the nucleus. The stellar and gas dynamics indicate that NGC 5077 has had at least two external interactions, one that resulted in the formation of the counter-rotating core, followed by the second, late-time external gas accretion. NGC 5077 illustrates the importance of external interactions in the replenishment of the galaxy gas reservoir and the nuclear gas content available for black hole fuelling.

Key words. black hole physics – quasars: supermassive black holes – galaxies: active – galaxies: elliptical and lenticular, cD – galaxies: individual: NGC 5077 – galaxies: kinematics and dynamics

1. Introduction

Counter-rotating or strongly misaligned structures of gas or stars are fairly common in early-type galaxies (e.g. Franx & Illingworth 1988; Kannappan & Fabricant 2001; Falcón-Barroso et al. 2004; McDermid et al. 2006; Sil’chenko et al. 2009; Krajnović et al. 2011; Raimundo et al. 2017; Johnston et al. 2018). Stellar kinematically distinct cores (KDCs) – that is, misaligned cores of stars that show an abrupt change of more than 30° in their kinematic axis (Krajnović et al. 2011) – are found in ~13% of the ATLAS 3D sample of early-type galaxies (Ebrová et al. 2021 and references therein). The presence of misaligned ionised or molecular gas (kinematic misalignment angles of more than 30° with respect to the stellar main body rotation) is also common. Out of the early-type galaxies with gas detections, which correspond to ~70% of galaxies in the ATLAS 3D sample, 41% show misaligned gas (Davis et al. 2011). S0 galaxies, in particular, tend to have a large fraction of gas in counter-rotation (~20–40%; e.g. Kuijken et al. 1996; Pizzella et al. 2004; Bureau & Chung 2006; Katkov et al. 2014). Counter-rotation corresponds to a kinematic misalignment of 180° between the stellar and gas kinematic angles and is likely caused by the stellar discs, which tend to align externally accreted gas either in co-rotation or counter-rotation (e.g. van de Voort et al. 2015). The presence of misaligned structures is a clear indication that the galaxy underwent an external accretion event (Bertola et al. 1992; Davis & Bureau 2016), such as a major or minor merger, gas transfer from a neighbour galaxy, or gas accretion from the immediate environment triggered by a flyby or by the accretion of primordial gas through large-scale filaments. This is because the gas that originates from stellar mass loss is expected to co-rotate with the stars. To change the angular momentum of a large mass of gas and create large kinematic misalignments or counter-rotation, a significant amount of energy would be needed, which is unlikely to be met by secular processes in the galaxy (e.g. Dumas et al. 2007; Davies et al. 2014). For galaxies with a low content of native gas, such as some early-type galaxies, the external accretion of gas may provide the necessary fuel to promote one or more episodes of star formation (e.g. Kaviraj 2014; Davis & Young 2019) or to fuel an active galactic nucleus (AGN; Raimundo et al. 2017). It has been shown from numerical simulations that the presence of misaligned or counter-rotating structures is associated with the flow of gas towards the nucleus and the potential fuelling of the AGN (e.g. Negri et al. 2014; Capelo & Dotti 2017; Taylor et al. 2018). One of the best observational examples of such phenomena is the active galaxy MCG–6–30–15, where the entire reservoir of gas available for AGN fuelling consists of counter-rotating gas (Raimundo et al. 2017). The detection of counter-rotating molecular gas in the nucleus of this galaxy indicates that an external accretion event was able to drive gas to the
innermost regions of the galaxy, which fulfills two of the requirements thought to be necessary for AGN fuelling: the presence of gas and the dynamical mechanisms necessary to transport the gas to the black hole (e.g. Storchi-Bergmann & Schnorr-Müller 2019 and references therein).

MCG–6-30-15 was, until now, the only active galaxy for which a detailed study of the stellar counter-rotating core, the counter-rotating gas dynamics, and the impact on black hole fuelling had been carried out (Raimundo et al. 2013, 2017). Identifying galaxies with counter-rotating gas is mostly done serendipitously (e.g. Raimundo et al. 2013). We have started a study of counter-rotating gas in the nuclei of galaxies to investigate the hypothesis that external gas accretion can replenish the AGN fuelling reservoir at scales of tens to hundreds of parsecs. The target of the present work, the galaxy NGC 5077, is known to have an active nucleus with characteristics of low-ionisation nuclear emission-line regions (LINERs) and to have ionised gas that is kinematically misaligned with respect to the main stellar body of the galaxy (e.g. Raimundo et al. 2014). The particular stellar and gas configuration and the presence of the ionising radiation from the AGN provide an opportunity to study the external accretion event and the AGN properties in this galaxy.

In this work we use, for the first time, integral field spectroscopy data of NGC 5077 to determine the full extent, dynamics, and excitation mechanisms of the ionised gas and to constrain the properties of the external accretion event.

2. Target and data analysis

NGC 5077 is an early-type galaxy classified as S0 according to the Revised Shapley-Ames Catalog (RSA) Catalog (Sandage & Tammann 1987; Temi et al. 2007) and is the brightest of a small group of eight galaxies (e.g. Sánchez-Portal et al. 2004; Tal et al. 2009) in a group environment with density \( \rho = 0.23 \) galaxies/Mpc\(^3\) (Annibali et al. 2010). It is located at \( z = 0.00936 \), corresponding to a physical scale of 220 pc arcsec\(^{-1}\) and a luminosity distance of 46.4 Mpc. It has a low-level AGN with LINER properties (Zhang et al. 2008; Annibali et al. 2010). The black central hole has a large mass and is one of a limited number of supermassive black holes with a dynamically measured mass: \( M_{\text{BH}} = 8.55^{+4.35}_{-4.45} \times 10^{6} M_{\odot} \) (de Francesco et al. 2008, for the cosmology parameters used in Kormendy & Ho 2013). There are several indications that NGC 5077 underwent an external accretion event: The overall ionised gas distribution has a polar configuration, approximately orthogonal to the stellar major axis (Bertola et al. 1991). There is also a counter-rotating stellar core in the nucleus (Caon et al. 2000), and faint dust lanes and filaments are observed (Tran et al. 2001; Simões Lopes et al. 2007), which is suggestive of a past external interaction.

We used archival data on NGC 5077 from the MUSE optical integral field spectrograph on the Very Large Telescope (VLT; Programme ID: 094.B-0298) to investigate the stellar and gaseous properties of the galaxy. The data were processed using the command line tool ESOREX (version 3.12.3) and the ESO recipes for the MUSE pipeline (version 2.2.0; Weilbacher et al. 2014). The procedure for data reduction was similar to what is described in detail in Raimundo et al. (2019). The only difference was the sky correction. As there are no sky exposures, we used a dark region of the field of view and a sky mask to do the sky correction during the recipe MUSE_SCIPST. The final cube had a spatial and spectral dimension of 321 \( \times 312 \times 3681 \) pixels, covering a field of view of \( 1.1 \times 1.1 \) arcmin\(^2\), which corresponds to \( \sim 13 \times 13 \) kpc at the redshift of NGC 5077. The pixel spatial sampling was 0.2 \( \times 0.2 \) arcsec\(^2\), and the spectral sampling was 1.25 Å. The wavelength range covered by the observations was 4750–9350 Å, and the spatial resolution of the data was estimated to be 0.8 arcsec from a star that is observed south-west of the galaxy. The median spectral resolution across the field of view was \( \sigma = 60 \pm 6 \text{ km s}^{-1} \) (FWHM = 2.6 Å) at \( 5577 \pm \sigma = 44 \pm 8 \text{ km s}^{-1} \) (FWHM = 2.37 Å) at 6923 Å, and \( \sigma = 37 \pm 4 \text{ km s}^{-1} \) (FWHM = 2.42 Å) at 8399 Å based on the fitting of un-blended sky lines (Raimundo et al. 2019).

To increase the signal-to-noise ratio (S/N) of the data, we produced two spatially binned data cubes using the Voronoi binning technique described by Cappellari & Copin (2003). The first data cube was binned based on the S/N level of the continuum at 5500 Å, to a minimum S/N \( \sim 50 \) per spatial pixel (i.e. S/N = 40/Å) to determine the stellar kinematics. To determine the stellar kinematics, we used the latest Python implementation of the Penalized Pixel-Fitting (pPXF) method (van der Marel & Franx 1993; Cappellari & EMSellem 2004; Cappellari 2017), with the full suite of stellar templates from MILES (Sánchez-Blázquez et al. 2006; Falcón-Barroso et al. 2011) to determine the stellar line of sight velocity distribution (for more details, see Raimundo et al. 2019). Since the stellar and gas spatial distributions are roughly orthogonal, we found that binning the data cube based on the continuum S/N resulted in a loss of spatial resolution in the regions of low stellar flux but still strong gas emission. Therefore, we created a second spatially binned cube based on the S/N in the Ha line measured in the pure gas emission cube (calculated by subtracting the best-fit pPXF model for the stellar emission from the observed spectra). We used an approach similar to that in Rosales-Ortega et al. (2012) but for the [N II] line complex. We identified a spectral band that covers the Hα+[N II] emission, with a width of 80 Å centred at the peak of the Hα emission lines, and two adjacent spectral bands that cover the continuum (i.e. line-free emission). We then defined the signal in the emission features as the mean of the difference between the pixel flux values within the emission spectral band and the mean of the fluxes in the two continuum bands, divided by the square root of the number of spectral pixels in the emission band. The noise was determined from the MUSE pipeline data reduction, which provides a cube with the variance in each spatial and spectral pixel. To determine the ionised gas dynamics, we used the available feature in the latest implementation of pPXF, which allowed us to simultaneously fit the stellar features and emission lines using a set of Gaussian templates. More details are presented in Sect. 3.3.

3. Results and discussion

3.1. Stellar kinematics

We show the results of the pPXF stellar kinematics analysis in Fig. 1. The stellar light distribution in the galaxy is relatively smooth, as can be seen from the light contours (integrated in the full MUSE spectral range) in the left panel of Fig. 1. The central and right panels of Fig. 1 show the stellar line of sight velocity and stellar velocity dispersion, respectively. The stellar rotation velocity is low, with values up to \( \sim 50 \text{ km s}^{-1} \). The stellar velocity dispersion is higher in the centre of the galaxy (250–300 km s\(^{-1}\) in the central 10 arcsec) and along the major axis, and lower along the minor axis of the galaxy. The region of high velocity dispersion coincides with the presence of a KDC, clearly seen in the flip of the direction of the velocity vector in the middle panel of Fig. 1. This KDC has also been seen by Caon et al. (2000), and we determined its diameter to be 12.6 arcsec and its spatial resolution in the regions of low stellar flux but still strong gas emission. Therefore, we created a second spatially binned cube based on the S/N in the Ha line measured in the pure gas emission cube (calculated by subtracting the best-fit pPXF model for the stellar emission from the observed spectra). We used an approach similar to that in Rosales-Ortega et al. (2012) but for the [N II] line complex. We identified a spectral band that covers the Hα+[N II] emission, with a width of 80 Å centred at the peak of the Hα emission lines, and two adjacent spectral bands that cover the continuum (i.e. line-free emission). We then defined the signal in the emission features as the mean of the difference between the pixel flux values within the emission spectral band and the mean of the fluxes in the two continuum bands, divided by the square root of the number of spectral pixels in the emission band. The noise was determined from the MUSE pipeline data reduction, which provides a cube with the variance in each spatial and spectral pixel. To determine the ionised gas dynamics, we used the available feature in the latest implementation of pPXF, which allowed us to simultaneously fit the stellar features and emission lines using a set of Gaussian templates. More details are presented in Sect. 3.3.
the KDC and of the main stellar body of the galaxy using the method from Krajnović et al. (2006) implemented in the routine FIT_KINEMATIC_PA as used by Cappellari et al. (2007). The KDC is consistent with a misalignment of 180° (i.e. counter-rotation), with a kinematic PA of 209.5 ± 22.5°; for comparison, the kinematic PA of the main body of the galaxy is 17.5 ± 2.5°. The high velocity dispersion observed in the core indicates the presence of random stellar motions along the line of sight; this is likely due to the large mass of NGC 5077, but it is also possible that the inferred high velocity dispersion is partially the result of the superposition of orbits from the co-rotating and counter-rotating stars.

3.2. Stellar and gas misalignment

Extended ionised gas emission is detected in NGC 5077 with a distribution that is significantly misaligned with respect to the main stellar body of the galaxy, and it is distributed along the galaxy’s apparent minor axis, as also noted in previous work (Bertola et al. 1991). The MUSE data allowed us to determine, for the first time, the extent of the gas distribution and the two-dimensional gas velocity map. In Fig. 2 we show the ionised gas distribution as traced by the total emission in the wavelength region of the Hα, [N II] at 6563 and [N II] at 6548,6583 emission lines, similar to what was done to calculate the S/N of the emission features (Sect. 2). The map in Fig. 2 shows the S/N of the total emission per unbinned spatial pixel within this wavelength band, with the spatial pixels with S/N < 3 masked out. Figure 2 is mostly for visualisation purposes since it highlights pixels where significant signal is detected and illustrates the filamentary morphology of the ionised gas distribution. Bertola et al. (1991) estimated a total extent for the ionised gas of 30 × 15 arcsec. We find that the extent is actually almost twice as large, with ionised gas observed out to the edge of the field of view of our data cube, to a projected distance of ∼ 30 arcsec (6.5 kpc) from the nucleus. With the current data we cannot determine if the emission extends further out beyond our field of view as we are limited by the noise at the edge of the MUSE field of view and the size of the field of view itself.

The strong misalignment between stellar and gas distribution can be clearly seen in Fig. 2, where we overlap the contours for the integrated light on the ionised gas emission. The large-scale gas distribution is filamentary and clumpy and is distributed almost perpendicularly (in projection) to the stellar distribution. There are several changes of the gas distribution PA as a function of radius: There is a change in PA at r > ∼ 4 arcsec from the centre, when the gas becomes almost perpendicular to the major axis of the galaxy, and then at r > 10 arcsec. The gas emission for r > 10 arcsec starts following what appears to be tidal features seen in projection, with spiral-like regions of increased gas emission. The smaller radius regions have a lower PA offset from the stellar kinematic PA. On the west side, the spiral arm is more pronounced, extending to the north and showing a filamentary structure surrounded by low-level emission with an orientation parallel to the major stellar axis of the galaxy (as seen in projection). On the east side, the emission is also filamentary and extends in two directions, a stronger component to the south and a weaker component with bright spots in the north-eastern direction. Previous work by Caon et al. (2000) detected extended gas emission but not the extended filamentary emission that we see in the north-south direction both east and west of the nucleus.

3.3. Ionised gas dynamics

48,6583, and [SII] λ6716,6731) that trace ionised gas. We start by analysing the emission features in the nuclear spectrum. In Fig. 3 we show the nuclear spectrum (solid black line) and the result of the pPXF best-fit model (solid red line) for that region. The individual emission lines are shown in orange and green, and the residuals from the fit are shown in grey at the bottom of each panel. We find that two sets of emission lines are needed to reproduce the observed spectrum in the nuclear region. One of the components is relatively narrow (shown in orange in Fig. 3), and the second component is broader (shown in green), redshifted by ~100 km s⁻¹ with respect to the systemic velocity of the galaxy and with a velocity dispersion of σ = 640 km s⁻¹ (FWHM = 1500 km s⁻¹). We find that this second component is present both in the Balmer lines and in the forbidden lines ([O III], [N II], and [S II]), indicating that it is not a manifestation of the broad line region of the AGN but most likely of the complex kinematics and non-circular motions in the narrow line region. Previous works (Balmaverde & Capetti 2014; Cazzoli et al. 2018) have also found evidence of this second component. The detection of a broad line region component, and hence the classification of NGC 5077 as a type 1 AGN, is, however, still a matter of debate. While Balmaverde & Capetti (2014) find that there is no secure detection of a third component (associated with the Hβ emission from the broad line region), Cazzoli et al. (2018) find that the addition of a broad Hβ component reduces the residuals in their fit. In this work we find that two components are able to reproduce the emission lines in the nucleus of NGC 5077, as can be seen in Fig. 3. While a weak broad emission line component may be present, our spectra do not show strong evidence for emission from the broad line region.

To determine the overall gas dynamics in the galaxy, we fitted the full data cube using pPXF. Since the stellar and gas distributions are not fully co-spatial, the size and spatial distribution of the bins for the two binned data cubes described in Sect. 2 are different. We therefore adopted an approach similar to that in Ganda et al. (2006) to ensure that the stellar contribution is accurately determined in regions of strong gas emission but weak stellar emission. The bins in the data cube binned as a function of S/N in the continuum will be called ‘star bins’, while the bins in the data cube binned as a function of S/N in the emission lines will be called ‘gas bins’. First, we fitted the stellar kinematics in the emission line binned data cube (i.e. the data cube binned as a function of the Hα+[N II] signal), using the best-fit stellar kinematics from Sect. 3.1 as starting values. The spectrum in each gas bin is calculated from the mean of the spectra in all the star bins that overlap with the gas bin. We used pPXF to determine the stellar kinematics in the gas bins, with the emission lines masked out of the fit. The stellar line of sight velocity moments from this fit are recorded and used as input for the subsequent analysis. The next step was to use the data cube binned as a function of the Hα+[N II] signal and to fit the stellar features and emission lines simultaneously. The stellar kinematics were held fixed to those determined in the step above, but the weights of each of the stellar templates and the additive Legendre polynomials were free to vary. We assumed the velocity and velocity dispersion of all the ionised gas species to be tied, and we used a single Gaussian component per narrow line, with the flux of each line as a free parameter, in the model. In the central regions of the galaxy we used a second, broader component for each line (as observed to be necessary in the spectrum of the nucleus; Fig. 3). We also used a reddening curve (Calzetti et al. 2000, with RV = 4.05) to account for the presence of dust, with E(B−V)gas as a free parameter in the fit and assuming the intrinsic Hα/Hβ flux ratio to be 2.86 (Osterbrock 1989).
In Fig. 4 we show the ionised gas velocity and velocity dispersion based on the results for the Hα narrow emission line. The second broader component ($\sigma \sim 640 \text{ km s}^{-1}$) is only detected in the nucleus, and we do not show it in the figures. A zoom-in of the central $10 \times 10 \text{ arcsec}^2$ narrow line emission is shown in the bottom panels of Fig. 4. The distribution of flux for the other species is shown in Fig. 5, and the line fluxes have been corrected for reddening using the output from pXF. Pixels where the amplitude-to-noise ratio in each line is $A/N < 5$ have been masked out in the figures, and all the maps shown have been smoothed using a boxcar filter (running mean) of $2 \times 2$ pixels, similar to the point-spread function (PSF) half width at half maximum.

![Fig. 4](image)

**Fig. 4.** Maps of ionised gas distribution and dynamics based on the Hα narrow emission. Top panels: full field of view and bottom panels a zoom-in of the inner $10 \times 10 \text{ arcsec}^2$; 10 arcsec corresponds to 2.2 kpc. From left to right: Hα flux, velocity, and velocity dispersion. The flux value is per spatial pixel ($0.2 \times 0.2 \text{ arcsec}^2$). The overlaid grey contours show the galaxy light isophotes, and the white contours are Hα flux contours. North is up, and east is left.

![Fig. 5](image)

**Fig. 5.** Flux maps for [O III], [N II], and [S II]. The figures only show regions where each of the lines was detected at an amplitude-to-noise ratio $A/N > 5$. The overlaid grey contours show the galaxy light isophotes. The orientation and scale is similar to that of Fig. 4.

In Fig. 4 we show the ionised gas velocity and velocity dispersion based on the results for the Hα narrow emission line. The second broader component ($\sigma \sim 640 \text{ km s}^{-1}$) is only detected in the nucleus, and we do not show it in the figures. A zoom-in of the central $10 \times 10 \text{ arcsec}^2$ narrow line emission is shown in the bottom panels of Fig. 4. The distribution of flux for the other species is shown in Fig. 5, and the line fluxes have been corrected for reddening using the output from pXF. Pixels where the amplitude-to-noise ratio in each line is $A/N < 5$ have been masked out in the figures, and all the maps shown have been smoothed using a boxcar filter (running mean) of $2 \times 2$ pixels, similar to the point-spread function (PSF) half width at half maximum.

The velocity map of the gas (Fig. 4) shows redshifted velocities east of the nucleus and blueshifted velocities west of the nucleus. The velocity profile is irregular in the central 8 arcsec along the major axis of the galaxy, a spatial region that coincides with the stellar counter-rotating core. As can be seen in the bottom panels of Fig. 4, the line of zero velocity has an S-shape: Increased velocity dispersion ($200$–$300 \text{ km s}^{-1}$) is observed in the nucleus and in a cone-shaped region towards the north out to a distance of $r \sim 3 \text{ arcsec}$ as well as towards the south, but with weaker emission. Increased velocity dispersion is also observed in two regions that extend out to $15$–$20 \text{ arcsec}$ to the east and to the west, with $\sigma \sim 100$–$200 \text{ km s}^{-1}$. A close inspection of the spectra in these regions of higher velocity dispersion shows that the increased velocity dispersion is not caused only by a broadened emission line (due to turbulent motions, for example) but by the superposition of more than one emission line component. It is likely that we are seeing different gas components along our line of sight, with slightly different velocities and locations.

Most of the gas is in the nucleus of the galaxy ($r < 10 \text{ arcsec}$ ~2.2 kpc). However, we detect faint tails that are separated by $180^\circ$ and are approximately symmetric. On the north side we see hints of a double tail. Additionally, we see regions of high gas velocity dispersion at $r > 5 \text{ arcsec}$ that are composed of double sets of emission lines, suggesting that we are seeing the superposition of two different gas components along our line of sight. Previous work suggested that the observed ionised gas lies in a warped polar ring (Bertola et al. 1991), which would give the gas emission a characteristic S-shape (e.g. van Albada et al. 1982). If that is the case, the tails would be caused by a warp in the gas.
3.4. Nuclear gas outflow

Figure 6 shows the spectrum of the region of high velocity dispersion north of the nucleus, corresponding to the integrated emission in a 1 × 1 arcsec² region, located 3 arcsec north of the nucleus. We modelled the spectrum from this region using a set of three gas components, which are necessary to reproduce the observed line emission. To verify that the data favour a model with three components instead of just two, we calculated the normalised residuals for the fit with two components and the fit with three components, given by (data–model)/1σ uncertainties, as in Eq. (13) of Andrae et al. (2010). We compared the distribution of residuals from each of the two models with a Gaussian distribution with mean μ = 0 and variance σ² = 1. To evaluate which of the models is a better representation of the data (and therefore the one for which the residuals match a Gaussian distribution best), we carried out a Kolmogorov–Smirnov test where we compared each of the model residuals to a Gaussian distribution and calculated the respective p-values. We found that the p-value for the three-component model is p = 7.346 × 10⁻⁴, compared with p = 2.8 × 10⁻³ for the two-component model. The higher p-value for the three-component model means that this model is a better representation of the data as its residuals more closely approximate a Gaussian distribution than those of the two-component model. One of the gas components (green line) has a relatively low velocity (v ~ 40 km s⁻¹, σ ~ 100 km s⁻¹), tracing a rotational component and matching the velocity of motion of the large-scale gas distribution perpendicular to the major axis of the galaxy (Fig. 4, bottom panel, centre). A second component (blue line) shows redshifted velocities of v = 430 km s⁻¹ and σ ~ 110 km s⁻¹, and a third component (orange line) shows blueshifted velocities of v = −380 km s⁻¹ and σ ~ 150 km s⁻¹. The blueshifted component is mostly detected at the edges of the high velocity dispersion cone. On the south side of the high velocity dispersion cone, ~2 arcsec south of the nucleus, the emission is dominated by the blueshifted component (v ~ −350 km s⁻¹) and the rotational component. The bicone geometry and the blueshifted and redshifted emission indicate that we are seeing an AGN-driven outflow. The lack of a young stellar population together with the geometry of the outflow disfavour a supernova-driven outflow. We observed both blueshifts and redshifts at the same position along the line of sight as well as more pronounced blueshifted emission along the edges of the bicone, which is in agreement with models of AGN-driven outflows along a hollow bicone that intercepts the plane of the sky (e.g. Bae & Woo 2016; Venturi et al. 2017). In Fig. 7 we show the flux, velocity, and velocity dispersion of the one-component fit to the [O III] emission in the nucleus where the outflow is more clearly visible.

Due to the complexity of the line emission and limited S/N, it is not possible to separate the line emission into individual emission components in every spatial bin. To show the velocity distribution of the gas we use the [O III] emission line, which has the advantage of not being affected by contamination from neighbouring lines, as opposed to [N II] and Hα. Figure 8 shows the [O III] integrated emission in velocity bins of 200 km s⁻¹, with the rest-frame 5007 Å corresponding to velocity zero. Only emission above 2σ is integrated to avoid adding noise. As can
be seen in the panels of Fig. 8, the [O III] has a complex velocity structure. The broad emission in the nucleus can be clearly seen in all panels, extending from the $-600$ km s$^{-1}$ to the $800$ km s$^{-1}$ velocity bin, in agreement with the large velocity dispersion and 100 km s$^{-1}$ redshift detected in the nuclear gas emission (Sect. 3.3). The blueshifted part of the outflow can be seen in the top left panel, in the regions of emission north and south of the nucleus, and along the direction of the stellar counter-rotating core (PA $\sim 209^\circ$). The redshifted part of the outflow is seen in the $+400$ km s$^{-1}$ and $+600$ km s$^{-1}$ panels, north of the nucleus. It is also clear that the extended emission to the west (seen in the $-400$ km s$^{-1}$ and $-200$ km s$^{-1}$ panels) has a higher absolute velocity than the extended emission to the east (seen in the $+200$ km s$^{-1}$ panels); this suggests that the overall gas motion has a small blueshifted offset, which, in turn, means that the gas velocity distribution is kinematically asymmetric (e.g.
Chung et al. (2012) or that a gas component is located in the foreground of the galaxy, between the galaxy and the observer. It is not clear if the broad velocity component ($\sigma \sim 650 \, \text{km} \, \text{s}^{-1}$) detected in the nucleus is the base of the outflow. This is likely the case since it is redshifted by $100 \, \text{km} \, \text{s}^{-1}$. If it is indeed the case, the outflow accelerates from the nucleus until the position of maximum blueshifted and redshifted velocities observed in Fig. 8. Since the nuclear broad velocity component is mostly confined to a spatial region consistent with the size of the PSF, it is likely unresolved in our observations, and the high $\sigma$ could be due in part to complex dynamical motions in the central 100 parsecs of the galaxy.

We compared the ionised gas emission with the dust distribution in NGC 5077. We used a *Hubble* Space Telescope (HST)/Wide Field and Planetary Camera 2 archival image of NGC 5077 using the F702W filter to map the distribution of dust in the galaxy. Figure 9 shows the image residuals after subtracting isophotes from the HST image. The residuals with dark colours highlight regions of obscuration by dust and clearly show the filamentary nature of the dust in NGC 5077, consistent with a previous occurrence of an external accretion event. The white contours show the ionised gas distribution and correspond to S/N levels of 5, 8, 10, and 25 in the H$\alpha$+[N II] emission of Fig. 2. The green contours show the location of the highest velocity dispersion gas, corresponding to $\sigma = 200 \, \text{km} \, \text{s}^{-1}$ and $\sigma = 250 \, \text{km} \, \text{s}^{-1}$ in Fig. 4. In the east-west direction, the dust distribution and the regions of higher ionised gas flux (shown with the white contours) are co-spatial, suggesting that they have a similar origin. There is an additional dust component along the major axis of the stellar light distribution (north-south) in the same direction as the outflow. In this direction, the inner regions of the outflow cone (shown by the green contours of increased velocity dispersion) are aligned with the north-south nuclear dust distribution. This can be more clearly seen in the region located at $\sim 2$–3 arcsec north of the nucleus, where the northern part of the outflow overlaps with a region of dust absorption (shown by the dark brown colours in Fig. 9). Dust has been observed to be carried by outflows from the AGN (e.g. Baron et al. 2018); it may be obscuring part of the outflowing gas emission, in particular in the south of the nucleus, where the outflow is not detected beyond 800 pc from the nucleus.

The outflow cone must intersect the plane of the sky due to the observed blueshifted and redshifted emission corresponding to the front and back sides of a hollow outflow cone. The northern part of the outflow is dominated by the redshifted emission, while the southern part is dominated by the blueshifted emission, which means that the southern part of the outflow is pointing towards the observer. The material in the outflow likely originates in the disc of the galaxy and is being driven outwards by the AGN, meaning that the outflow cone partially intersects the disc of the galaxy. The gas and dust in the disc of the galaxy may be a remnant of the external interaction that created the counter-rotating stellar core.

Filho et al. (2006) detected two very strong radio sources in the nuclear regions of NGC 5077 using high spatial resolution observations. The authors noted that without spectral information they could not identify the origin of the radio emission (i.e. if it is coming from the AGN). We show the position of the radio sources overlaid with the [O III] velocity dispersion in the right panel of Fig. 7. The coordinates for the radio emission are as given in Table 3 of Filho et al. (2006), while the [O III] reference frame is that of the MUSE data cube, which matches the coordinates of the HST images and *Gaia* DR3 source positions. Filho et al. (2006) found these radio knots to be extended; however, considering the high spatial resolution of the radio observations ($\sim 0.1$ arcsec), we can see that the radio emission originates from outside the nucleus of the galaxy (i.e. the peak of gas emission and stellar light). The radio emission is spatially located in the region of the blueshifted part of the outflow. In AGN-driven outflows, there is often a similar orientation of radio emission and outflow, as we see here in NGC 5077, but not a perfect spatial correlation (Müller-Sánchez et al. 2011; Fischer et al. 2019). The radio emission is in some cases associated with a jet that is interacting with the interstellar medium and transferring angular momentum to the gas to power the AGN outflow. In the case of NGC 5077, the radio emission may be caused by synchrotron emission from relativistic particles that are accelerated in the shocks caused by the AGN outflow (e.g. Zakamska & Greene 2014; Fischer et al. 2019).

### 3.5. Excitation mechanisms

We used the observed spatially resolved narrow emission line fluxes to investigate the excitation mechanisms at work in NGC 5077. The diagnostics we used are based on line flux ratios (Baldwin et al. 1981; Veilleux & Osterbrock 1987), also known as BPT diagrams (Fig. 10). We only included spatial bins where all the diagnostic lines were detected above an amplitude-to-noise ratio level of $A/N > 3$. H$\beta$ is the weakest line and therefore the main factor in constraining the spatial regions where the BPT analysis can be carried out. In general, H$\beta$ and [O III] are much weaker than H$\alpha$ and [N II]. Panel a of Fig. 10 shows the spatial regions analysed, colour-coded to facilitate the reading of the BPT diagrams. Panels b and c show the [O III] $\lambda$5007/H$\beta$ versus [N II] $\lambda$6583/H$\alpha$ and the [O III] $\lambda$5007/H$\beta$ versus [S II] $\lambda$6716 + $\lambda$6731/H$\alpha$ diagnostics, respectively. To identify excitation mechanisms based on these line ratios, we used the theoretical regions defined by Kewley et al. (2006), which are shown as solid and dashed lines in panels b and c of Fig. 10.

As can be seen from the location of the points in panels a–c of Fig. 10, the line ratios are consistent with the excitation...
The conditions of LINERs for most of the regions in NGC 5077. Part of the outer regions ($r > 10$ arcsec, 2.2 kpc) may also have some contribution of star formation, in addition to the AGN, based on panel a. While LINER-like excitation is typically caused by shocks or a (low luminosity) AGN, for some galaxies the LINER-like excitation is due to the presence of stars in the post-asymptotic giant branch (post-AGB) phase (e.g. Stasińska et al. 2008; Singh et al. 2013; Levan et al. 2017). The argument is that in the post-AGB phase the stars become sufficiently hot to generate ionising photons that are able to produce LINER-like emission (Binette et al. 1994). If this is the case, it means that the stars responsible for the gas excitation must be older than 1 Gyr.

As a second diagnostic we determined the equivalent width of the narrow component of the Hα line ($W_{\text{H\alpha}}$) to build a WHAN plot of $W_{\text{H\alpha}}$ versus [N II]/Hα (Cid Fernandes et al. 2011), which has shown to be a good discriminator between excitation by AGNs and excitation by post-AGB stars (Cid Fernandes et al. 2010). This diagnostic is also especially valuable for galaxies with weak lines (Cid Fernandes et al. 2011), which is the case for Hα in NGC 5077. The equivalent width is determined from the Hα flux and the continuum of the spectral fitting, but similar results are obtained when integrating the narrow Hα emission directly in the spectrum. Panel d of Fig. 10 shows the Hα equivalent width as a function of [N II]/Hα (‘WHAN’) diagram. The labels and the solid or dashed lines indicate the plausible excitation mechanisms in each region of the diagram (see the text for a description). The coloured symbols match the line ratios measured for the corresponding colour-coded regions of the left panel. The diagrams show that there is a dominant contribution of AGN excitation in most of the regions (green circles and light blue crosses). The dark blue crosses show regions where post-AGB stars make an equal or larger contribution than the AGN to the ionising field.

3.6. Stellar population

We used the stellar population synthesis code STARLIGHT (Cid Fernandes et al. 2005, 2009) to model the stellar population age and metallicity in the galaxy to determine if there is evidence of recent star formation. We used the set of theoretical stellar spectral templates from the E-MILES evolutionary population synthesis models (Vazdekis et al. 2016), which cover a range of stellar ages (0.0631–17.7828 Gyr) and metallicities ($-2.32 < [\text{Fe/H}] < 0.22$). The procedure for the modelling is similar to that described in Raimundo et al. (2019) for the AGN host Mrk 590. More details can be found there as well as in Cid Fernandes et al. (2004, 2005), and references therein. We used as input the data cube binned to a minimum S/N of 50 and modelled the spectrum for each bin. We assumed a Calzetti dust reddening curve (Calzetti et al. 2000) to model the host galaxy reddening, and STARLIGHT fits the V-band continuum extinction ($A_V$) at each spatial bin. The fitted wavelength range is 4644–9000 Å. Figure 11 shows the results of the modelling: the luminosity-weighted mean stellar age ($\langle \text{log} \ t \rangle$) in the left panel, the luminosity-weighted mean metallicity ($\langle Z \rangle$) in the central panel, and $A_V$ in the right panel. Our results of an old stellar population in the nucleus of the galaxy agree with those found by Annibali et al. (2007), who used long-slit spectroscopy to match the line ratios measured for the corresponding colour-coded regions of the left panel. The diagrams show that there is a dominant contribution of AGN excitation in most of the regions (green circles and light blue crosses). The dark blue crosses show regions where post-AGB stars make an equal or larger contribution than the AGN to the ionising field.
determine the stellar population within a radius of 2.85 arcsec from the centre. We find that there is a slight negative gradient of stellar age outside the nucleus. We observe a younger stellar population with age (log t) lower than ten outside the nucleus. We note that the modelled stellar age and metallicity are less reliable in the outskirts of the galaxy, and for this reason in Fig. 11 we only show the results from STARLIGHT for the central regions of the galaxy, where the stellar flux is greater than 1% of the peak flux. There is no evidence of recent (<1 Gyr) star formation in the galaxy, and the stellar population is dominated by old stars. From our analysis, the age of the stellar counter-rotating core is similar to or slightly older than the stellar age in the main body of the galaxy, which points towards an early formation of the counter-rotating core. It is expected that the stellar population difference between KDCs and the main body of the galaxy is diluted by time, beginning from the original accretion event (McDermid et al. 2006). This finding also supports the possibility that two external accretion events took place: one that formed the stellar counter-rotating core and a more recent one that resulted in the accretion of the decoupled distribution of ionised gas.

3.7. Origin of the gas

Due to the dynamical configuration observed, with the gas significantly misaligned and in a polar configuration with respect to the major axis of the galaxy, the origin of the gas can be clearly identified as external, as also seen for several other galaxies in similar configurations (e.g. Sil’chenko et al. 2019; Gnilka et al. 2020), since secular processes are not able to explain large quantities of misaligned gas (Caldwell et al. 1986; Kannappan & Fabricant 2001). The properties of NGC 5077 match the predictions from numerical simulations by van de Voort et al. (2015) rather well, where an early-type galaxy can show a misaligned gas distribution caused by late-time gas accretion after a gas-rich major merger. This is, to the best of our knowledge, the first time that the van de Voort et al. (2015) prediction of a warped misaligned gas disc has been confirmed by observations.

van de Voort et al. (2015) carried out a numerical simulation, as part of the Feedback in Realistic Environments (FIRE) simulations Hopkins et al. (2014), of an early-type galaxy that underwent a major merger event (1:4 stellar mass ratio with a gas-rich galaxy). They predicted that the merger would cause a strong inflow of gas followed by strong outflow, where gas is pushed out of the galaxy (and a significant fraction is actually expelled). Roughly 0.5 Gyr after the merger, the galaxy starts a late-time accretion of misaligned gas, gas leftover from the major merger as well as gas from minor satellites. Once the amount of accreted gas decreases, the gas starts its process of gravitational relaxation and forms a misaligned warped disc (Fig. 1 of van de Voort et al. 2015). The warp in the disc is caused by the gravitational torques of the stellar potential. In an axisymmetric potential, a gravitational torque from the stars will act on the gas; this torque is larger at smaller radii and therefore causes the realignment to happen faster in the nucleus. Since the gas is subject to dissipative forces, it will collide and reduce its angular momentum until it is in one of the most stable configurations, co-rotating or counter-rotating with the stars (e.g. van de Voort et al. 2015). The result is that before the gas reaches a stable configuration, it will go through a relatively long phase (~2 Gyr) in a misaligned warped disc, with changes in the PA of the gas as a function of radius, due to the fact that the centre of the disc aligns faster than the outskirts. This is similar to what we observe in NGC 5077. The gas distribution in NGC 5077 is significantly misaligned from the stellar major axis, with the inner regions of the gas disc showing a smaller angular misalignment than the outer regions. Below we summarise the observations of NGC 5077 that match what is predicted by the simulations of van de Voort et al. (2015).

The stellar counter-rotating core in NGC 5077 has an old stellar population and a large diameter, typical of the KDCs found in slowly rotating galaxies (McDermid et al. 2006). Such KDCs are formed at early epochs (via a major merger or in situ star formation after the accretion of gas), and no difference is expected to be seen in terms of the stellar population age (McDermid et al. 2006). Counter-rotating stellar cores or KDCs can be long-lived and survive subsequent merger or gas accretion events (Ebrová et al. 2021). A KDC is also seen in the simulation of van de Voort et al. (2015). It is then likely that the ionised gas distribution we see now has been formed from a more recent accretion event (after the major merger, as hypothesised by van de Voort et al. 2015). This is also supported by the irregular gas velocity profiles we observe that indicate that at least part of the gas is not in equilibrium.

The stellar distribution of the galaxy is smooth (Fig. 1), with a regular velocity field, and currently shows no signs of having been disrupted by a gravitational interaction. We also do not detect a significant stellar component associated with the polar gas distribution, which would have been expected for the case of a recent major merger with another galaxy (e.g. Tal et al. 2009) or by strong tidal interactions. In the scenario of van de Voort et al. (2015), this is expected since they estimate that the signatures of the merger (shells and tidal tails) disappear before the gas aligns with the disc. Gas misalignments are not expected to be associated with merger signatures in the
stellar photometry. It is possible that there is a low luminosity diffuse stellar component that we do not detect, for example after one of the minor mergers, as stars in low-mass satellite galaxies can be easily torn during the merger and spread out into the stellar halo (e.g. Bullock & Johnston 2005). Gas is more susceptible to perturbations due to its dissipative nature; it can be perturbed or transferred from another galaxy during a close encounter or accreted from nearby gas triggered by a flyby (Kannappan & Fabricant 2001), without necessarily involving stellar perturbations. The metallicity of the gas is also what we expect from a merger, not what we would expect from infall of primordial gas through filaments. We detect significant amounts of [N II] in almost all regions where Hα is also detected. The line ratio [N II]/Hα is typically >0.5, as can be seen in Fig. 10, and oxygen lines are detected, which indicates that the gas is not primordial (e.g. Caldwell et al. 1986; Watkins et al. 2018). This suggests that what we are seeing is not infall of gas through a filament but accretion of gas from leftover material from a major merger event, transfer from a neighbour galaxy, or the disruption and accretion of a low-mass satellite galaxy.

The simulated early-type galaxy from van de Voort et al. (2015) is in a dense group, which acts as the source for the late-time gas accretion (mainly through the accretion of satellites). NGC 5077 is also located in a group of galaxies that is not covered by the field of view of the MUSE data. In Fig. 12 we show the neighbouring region of NGC 5077, from a Digitized Sky Survey 2 (DSS2) I-band image. The top panel shows the group of galaxies Holm 514, of which NGC 5077 is a member, together with NGC 5076 and NGC 5079. The bottom panel is a zoom-in of the top panel, showing NGC 5077 with contours overlaid and a fourth group member, Holm 514D, highlighted with a red circle. The other point sources are foreground stars. Based on the orientation of the tails of ionised gas, both Holm 514D and NGC 5079 are candidates for having provided some of the gas for NGC 5077 or for flybys that triggered the accretion of gas from the outskirts of NGC 5077 (leftover gas from a major merger, for example). NGC 5079 is a barred spiral galaxy (SB(rs)bc pec; de Vaucouleurs et al. 1991) at a projected distance of 40 kpc and \(v_{\text{sys}} = 2242 \text{ km s}^{-1}\), while \(v_{\text{sys}} = 2806 \text{ km s}^{-1}\) for NGC 5077. The estimated neutral hydrogen (HI) mass of NGC 5079 is \(\sim 10^9 M_\odot\) (Bottinelli et al. 1982, although the source is possibly confused in their measurements). Radio observations at 1.4 GHz show that the emission in NGC 5077 is extended in the direction of NGC 5077 (Wrobel & Heeschen 1984). In the case of spiral galaxies, the Hi gas envelope is typically more extended than the stellar body, and that can explain why in tidal interactions or flybys the gas is stripped first (and not the stars; Chung et al. 2012). Spatially resolved observations of neutral gas (H I) would allow us to constrain the origin of the gas since gas transfer from companion galaxies typically shows HI bridges (Morganti et al. 2006).

The late-time gas accretion could have originated from the accretion of one or more small gas-rich satellite galaxies that have by now disappeared. That would explain the disturbance of the gas (but not the stars). There is an H α blob, a region of stronger Hα emission, at the edge of the MUSE field of view (shown as a red square in the left panel of Fig. 13). The excitation conditions are typical of star-forming regions, in contrast with the rest of the emission in NGC 5077, which is mostly consistent with LINER-like excitation conditions (Fig. 10). The region of strong Hα emission appears to be at the end of the weak filaments in Fig. 2 that extend from the east side of the nucleus towards the north-eastern edge of the field of view. This region is blueshifted with respect to the systemic velocity of the galaxy, with \(v = -310 \text{ km s}^{-1}\), indicating that it is either in the foreground of the galaxy or moving towards the observer. It also shows very low velocity dispersion (\(\sigma = 19 \text{ km s}^{-1}\)). It is not clear if the Hα blob is a remnant of a disrupted gas-rich satellite that has been accreted by NGC 5077. As it is detected at the edge of the field of view, the low signal in the continuum does not allow us to detect a possible stellar population. Based on the Hα flux in this region, we calculated a total Hα luminosity \(L_{\text{Hα}} = 4.5 \times 10^{35} \text{ erg s}^{-1}\) in a 220 pc × 220 pc region, which corresponds to a star formation rate of \(2 \times 10^{-6} M_\odot \text{ yr}^{-1}\) using the relation from Kennicutt (1998). Targeted observations of the outskirts of NGC 5077 and its companion galaxies (Holm 514D) would allow us to investigate the origin of the gas observed in NGC 5077.

The ionised gas distribution somewhat resembles NGC 4993, the host of the binary neutron star merger GW170817 and an S0 galaxy that also underwent an external accretion event (Levan et al. 2017). These two galaxies share a number of characteristics, including the decoupling between gas and stars, the presence of dust lanes, the presence of spiral-like features in the gas emission, and the filamentary nature of the gas at large radii. We hypothesised that NGC 4993 may have had a similar history
of external accretion as that of NGC 5077, possibly explained by the scenario of van de Voort et al. (2015). The S0 galaxy Mrk 3 (Gnillka et al. 2020) is another example of a galaxy with a large decoupled distribution of gas and the presence of dust lanes caused by the accretion of gas from a companion galaxy. Such similarities point towards a common set of observables after an external accretion event in S0 galaxies.

3.8. Black hole fuelling

In terms of the consequences of this external accretion event for the black hole, we see that the external accretion event provided a fresh supply of gas to the galaxy. There is little gas co-spatial with the major stellar distribution, which indicates that even if there is some residual gas in the stellar disc, most of the gas in the galaxy has been externally accreted. Ionised gas is detected down to the spatial resolution of the data (FWHM = 0.8 arcsec, which corresponds to a radial distance of 0.4 arcsec ~90 pc from the nucleus) and shows misaligned motions. The nuclear gas appears to have a rotation component (Fig. 8) in addition to the outflow. The dynamics of the gas shows that it is being affected by the stellar gravitational potential of the disc and is losing angular momentum due to collisions as it aligns itself in a co-rotating or counter-rotating orientation with respect to the stellar rotation. Accretion of misaligned gas can then be an efficient way to drive gas to the nucleus and to promote the fuelling of the black hole. NGC 5077 has detections of prominent rotational $H_2$ lines in the mid-infrared (Panuzzo et al. 2011), a tracer of molecular gas. The mass of gas available for black hole fuelling can be determined from future observations of the molecular gas mass in NGC 5077.

In Fig. 12 we see that there are several X-ray point sources detected within the region of the galaxy (cyan circles), in addition to the X-ray emission coming from the nucleus of NGC 5077. While off-nucleus X-ray point sources may be caused by AGNs in the background of the galaxy, the closer the X-ray point sources are to the centre of the galaxy, the more likely it is that they are associated with NGC 5077. There is one X-ray point source (CXOGSG J131930.6–123925), identified as part of NGC 5077 (Wang et al. 2016), that has ionised gas significantly detected at its location. The position of this off-nucleus X-ray point source is indicated by a cyan circle in the three panels of Fig. 13. From the contours in the left panel of Fig. 13, we can see that the position of the X-ray point source corresponds to a region of increased $H_\alpha$ flux. The central and right panels of Fig. 13 shows the BPT and WHAN line diagnostic diagrams, which suggest that there are AGN-like excitation conditions at the X-ray point source position (cyan circle). The following is speculation, but one hypothesis to explain both the presence of off-nucleus X-ray emission and the AGN-like excitation conditions detected at its position is the accretion of gas (possibly promoted by the recent inflow of fresh gas into the galaxy) onto an offset intermediate or supermassive black hole. Such offset black holes are expected in galaxies in which a minor or major merger occurred (e.g. Comerford et al. 2009); however, it is not clear if that is what we are seeing in NGC 5077, and at the moment this is just a speculative hypothesis. Due to the low X-ray flux of the off-nucleus X-ray point source ($L_X = 4.75 \times 10^{38}$ erg s$^{-1}$; Wang et al. 2016), it could also have a stellar origin (e.g. be a bright X-ray binary or supernova) and coincide with a region of increased $H_\alpha$ flux and AGN-like excitation conditions.

Compared with MCG–6-30-15, the brightest AGN host with counter-rotating gas and stars (Raimundo et al. 2017), NGC 5077 appears to be at an earlier stage of the gas accretion process. In MCG–6-30-15 the ionised and molecular gas were aligned with the major axis of the galaxy but were counter-rotating. The only large-scale signature of interaction in MCG–6-30-15 was the presence of dust lanes. In NGC 5077 the accretion of gas is relatively recent, and the gas appears to still be settling, as seen from the changes in PA as a function of radius. Curiously, MCG–6-30-15 also showed an AGN-driven outflow. According to the scenario of van de Voort et al. (2015), MCG–6-30-15 could be in a later stage of the gas relaxation process that is currently occurring in NGC 5077. The AGN in MCG–6-30-15 is more luminous than that of NGC 5077, presumably having already been fuelled by the counter-rotating gas.

The large-scale AGN-like excitation conditions in NGC 5077 can indicate that the black hole had a burst of activity in the past, possibly right after the major merger. The simulations of van de Voort et al. (2015) show that there was a strong inflow of gas due to the first major merger, followed by an outflow that removed most of the gas from the galaxy. Some part of this gas could have fuelled the black hole for a short period of time. The misaligned gas that we currently see in NGC 5077 will continue to lose angular momentum and flow to the nucleus. The gas that we currently see in the nucleus may...
already be fuelling the black hole. It is expected that, as more
gas reaches the nucleus, the black hole fuelling reservoir will
significantly increase in mass (as seen in MCG−6−30-15) and
fuel the future AGN activity in the galaxy.

4. Conclusions

Externally accreted gas can replenish the internal gas reservoir
of early-type galaxies and may contribute to the fuelling of
the black hole. To investigate the presence of counter-rotating
structures in AGN host galaxies, we analysed observations of
NGC 5077, an S0 active galaxy that shows an extended and
dynamically decoupled distribution of ionised gas. Previous
work has sampled the ionised gas along the galaxy’s major and
minor axes, but this is the first time that the full extent and geo-
metry of the ionised gas distribution have been mapped and
analysed, and the origin of the misaligned gas constrained.

We confirm the presence of a stellar KDC, close to coun-
ter-rotation with respect to the main body of the galaxy, and with
a diameter of 2.8 kpc. The stellar age of the KDC is simi-
lar to that of the rest of the galaxy, indicating that it was not
formed recently as the difference in stellar age has been dilut-
ed. The galaxy shows low stellar velocity rotation ($v < 50$ km s$^{-1}$)
and an increased stellar velocity dispersion in the KDC ($\sigma \sim 250$–300 km s$^{-1}$). The gas distribution shows a strong warp
and decoupled dynamics and is detected out to ~6.5 kpc. The gas
velocity and velocity dispersion maps show complex dynamics
and evidence for various gas components with slightly differ-
ent velocities and positions along the line of sight. The gas PA
changes as it approaches the nucleus, in the direction of the rota-
tion of the stellar counter-rotating core. Gas is detected in the
nucleus, down to the spatial resolution of our data at a radius of
~90 pc from the central supermassive black hole. We detect
an AGN-driven outflow with a maximum projected velocity of
$V \sim 400$ km s$^{-1}$ in the north-south projected direction. The out-
flow geometry is a hollow bicone that intersects the plane of the
sky, with the southern portion of the bicone pointing in the direc-
tion of the observer. The dominant excitation mechanism of the
ionised gas is an AGN, based on the ionised gas line ratios and
the $H\alpha$ equivalent width. The AGN in NGC 5077 is currently
at a low luminosity level, $L_X(2-10$ keV) $\sim 6 \times 10^{39}$ erg s$^{-1}$
(Gültekin et al. 2012), but the large physical extent of the ionised
gas suggests that the AGN may have been more luminous in the
past.

We present, for the first time, observational evidence of the theo-
retical scenario proposed by van de Voort et al. (2015), where the accretion of misaligned gas can create a warped gas distribution,
with the central regions aligning first with the stellar rotation. Supported by the numerical simulations of van de Voort et al. (2015), the most likely scenario for NGC 5077 is that several gigayears ago it went through a major merger with another galaxy that resulted in the formation of the stellar
counter-rotating core we currently observed. Most of the major
merger gas was promptly removed, temporarily or permanently,
from the galaxy by supernova-driven outflows. Late-time accre-
tion (in the following 1–2 Gyr) of misaligned leftover gas from
the merger (possibly triggered by flybys) or the accretion of
small gas-rich satellites provided fresh gas to the galaxy. When
the accretion rate of gas decreased, the process of gas relax-
dation due to the stellar gravitational torques started to dominate,
causing a significant warp to the gas, with the smaller-radius
gas aligning first. This is the stage that we currently observe in
NGC 5077. It is expected that in the future the gas will continue
to lose angular momentum and end up in a stable configuration,
that is, co-rotating or counter-rotating in the same direction as
the stars – similar to what is currently observed in MCG−6−
30-15, an active galaxy with counter-rotating gas. The stellar
torques to the gas can be an efficient method to drive gas to the
nucleus and replenish the black hole fuelling reservoir.

NGC 5077 is part of an increasing number of active early-
type galaxies in which the majority of the observed gas
originated in an external accretion event. While the disturbances
cannot be immediately identified in a first look at the optical
broadband image of NGC 5077, ionised gas observations com-
bined with the presence of a stellar distinct core clearly show that
at least two accretion events have taken place. This highlights
the importance of external accretion events for the gas supply in
early-type galaxies and the replenishment of the reservoir of gas
available for black hole fuelling.

Acknowledgements. The author would like to thank the referee, for a thorough
review of the paper and for the constructive comments and suggestions that have
generated improved quality of this work. The author also thanks Mike Crenshaw, Ric Davies, Travis Fischer, Steven Kraemer, Joao Mendonca, and Marianne Vestergaard for useful discussions. This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 891744. Based on observations collected at the European Southern Observatory under ESO programme 094.B-0298. This research has made use of the services of the ESO Science Archive Facility. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. Based on observations made with the NASA/ESA Hubble Space Telescope, and obtained from the Hubble Legacy Archive, which is a collabora-
tion between the Space Telescope Science Institute (STScI/NASA), the Space
Telescope European Coordinating Facility (ST-ECF/ESA) and the Canadian Astronomy Data Centre (CADC/NRC-CSA). This research made use of Astropy (http://www.astropy.org), a community-developed core Python package for Astronomy (Astropy Collaboration 2013, 2018).
