Introduction: The exact dependence of biological effect on dose and linear energy transfer (LET) in human tissue when delivering proton therapy is unknown. In this study, we propose a framework for measuring this dependency using multi-modal image-based assays with deformable registrations within imaging sessions and across time.

Materials and Methods: 3T MRI scans were prospectively collected from 6 pediatric brain cancer patients before they underwent proton therapy treatment, and every 3 months for a year after treatment. Scans included T1-weighted with contrast enhancement (T1), T2-FLAIR (T2) and fractional anisotropy (FA) images. In addition, the planning CT, dose distributions and Monte Carlo-calculated LET distributions were collected.

A multi-modal deformable image registration framework was used to create a dataset of dose, LET and imaging intensities at baseline and follow-up on a voxel-by-voxel basis. We modelled the biological effect of dose and LET from proton therapy using imaging changes over time as a surrogate for biological effect.

We investigated various models to show the feasibility of the framework to model imaging changes. To account for interpatient and intrapatient variations, we used a nested generalized linear mixed regression model. The models were applied to predict imaging changes over time as a function of dose and LET for each modality.

Results: Using the nested models to predict imaging changes, we saw a decrease in the FA signal as a function of dose; however, the signal increased with increasing LET. Similarly, we saw an increase in T2 signal as a function of dose, but a decrease in signal with LET. We saw no changes in T1 voxel values as a function of either dose or LET.

Conclusions: The imaging changes could successfully model biological effect as a function of dose and LET using our proposed framework. Due to the low number of patients, the imaging changes observed for FA and T2 scans were not marked enough to draw any firm conclusions. © 2021 American Association of Physicists in Medicine [https://doi.org/10.1002/mp.14989]
1. INTRODUCTION

Proton therapy takes advantage of the finite range of protons, enabling sparing of normal tissue at the distal end of the treatment beam.1,2 There are, however, a number of geometric uncertainties related to treatment delivery, such as range- and setup-uncertainties,3-6 which may limit the clinical benefit. In addition, there are indications that the clinical standard assumption of a constant relative biological effectiveness (RBE) across the beam is not accurate, but rather depends on the local linear energy transfer (LET).7 More recently, clinical observations have supported this conjecture, for example using Monte Carlo simulation,8 retrospectively evaluating radiographic abnormalities in the chest wall,9 and modelling post-treatment image changes as delineated by a physician.10,11 The available data suggest that the biological effect of protons increases as the LET increase, typically towards the end of the beam. This may negate part of the beneficial effect of proton therapy unless properly accounted for in planning.

Various models have been suggested to describe a variable biological effect.8,9,12 However, these models are based on in vitro data, and the clinical data to validate them are missing. To transfer our understanding of variable biological effects to clinical treatment plan optimization, we need better estimates of the relationship between local effect, dose and LET, based on in vivo data. This includes dependence on tissue type, fractionation, alpha/beta ratio and other effects. To accurately model this, a framework for in vivo assessment of local biological effect is needed.

Imaging has been used as a marker for radiation damage in a number of settings, for example to assess treatment response,16,17 outcome predictions18 or for adaptive treatments.19,20 These studies use a variety of MRI, PET and CT images, and have been able to relate a per-voxel radiation dose to a local response. As LET has varying localized effects in vivo and because of inhomogeneous dose distributions, using imaging to investigate a variable biological effect of protons is an ideal choice. Fractional anisotropy (FA) imaging maps myelinated white brain matter, and it has been shown that FA maps loose signal due to radiation damage21-23 and that FA changes are associated with cognitive impair after trauma.24 A link between damage of white matter, following combined surgery and proton radiation and measured with FA maps, and cognitive performance has also been shown.25 It is plausible that the FA maps can serve to measure relevant components of the biological damage of radiation.

We therefore aimed to develop a multimodal imaging framework for modelling imaging changes over time on a voxel-by-voxel level, thus being able to link imaging changes (as a surrogate for biological effectiveness) to the dose and LET distribution. The framework takes inter- and intra-variation between patients into account by using a sophisticated deformable registration strategy between template time-points, where a template consists of different relevant imaging modalities acquired at the same timepoint. Our proposed method supports multimodal imaging, which we demonstrate using different magnetic resonance imaging (MRI) sequences and CT images.

2. MATERIALS AND METHODS

In brief, we enrolled patients in a prospective study to longitudinally assess normal tissue imaging response after proton therapy. A complex series of rigid and deformable registrations provided us with a voxel-by-voxel data set. Finally, three models of LET and dose dependence were chosen to show the ability of the imaging framework to describe imaging changes over time. We chose to use T1, T2 and FA MRI images in this study.

2.A. Patient cohort and image acquisition

For image-based quantification of local effect as a function of dose and LET, a robust data acquisition protocol is required. Pediatric brain cancer patients from the Capital Region of Denmark were prospectively included in a clinical study, approved by the regional Scientific Ethics Committee (H-3-2014-135). They were enrolled prior to referral for proton therapy, which was delivered at the MD Anderson Cancer Center, University of Texas, Houston, USA. Radiotherapy and chemotherapy protocols were in line with international standards for each cancer type.26,27 All patients were treated with passive scattering proton therapy. Initial assessment, adjuvant treatment, and follow-up were conducted at Rigshospitalet, Denmark. After informed consent by the patient or the patient’s guardian, we acquired dedicated study MRI scans of the patients before and after their proton therapy, alongside standard clinical imaging. The scans were acquired two weeks before proton therapy was initiated (baseline), and at follow-ups two months after proton therapy completion and then at three-monthly intervals for a year. The dedicated study MR protocol included the following standard clinical structural sequences: a T1 weighted magnetization-prepared rapid acquisition with gradient echo (MPRAGE, 1 mm × 1 mm × 1 mm voxel size) with contrast agent (gadolinium), and an axial T2 and coronal Fluid-attenuated inversion recovery (Flair, 0.7188 mm × 0.7188 mm × 6 mm voxel size). In the remainder of this paper, we will refer to these two sequences simply as “T1” and “T2”. Additional clinical sequences varied on a patient specific basis, for example T2 dark fluid sequences were included where appropriate. Further, we performed study protocol-specific MR diffusion tensor imaging (DTI) designed to measure myelinated...
white brain matter. The latter was made by measuring directional diffusion in thirty main directions. All other DTI parameters were equal with b value $= 1,000 \text{ mm}^{-2}$, repetition time/echo time $= 4900/90 \text{ ms}$, field of view $= 230 \text{ mm} \times 230 \text{ mm} \times 190 \text{ mm}$, acquisition matrix $= 128 \times 128 \times 37$ voxels, flip angle $= 90^\circ$. The three-dimensional directional diffusion images were used to create a FA map.\textsuperscript{17} MRI scans were performed on a 3 T Siemens Prisma Scanner (Siemens, Erlangen, Germany) using a 64-channel head coil or at a 3T Siemens Biograph mMR (Siemens, Erlangen, Germany) with a similar protocol. Corrections for motion and eddy currents of the FA map were done using FSL python library for DTI brain imaging data. As part of the proton treatment planning, all patients received a CT scan for dose calculations which was also included in the study. The planning CT scan was used for dose planning and LET calculation. One patient (patient 2) was also enrolled in a study of \textsuperscript{[18F]}FET PET/MRI examinations of patients with pediatric CNS tumors\textsuperscript{28} approved by the regional Scientific Ethics Committee (H-6-2014-095) and had two of his MRI scans performed at the PET/MRI scanner to reduce the number of scanning procedures. Example imaging and treatment information for one patient can be seen in Fig. 1.

2.B. Dose and LET calculation

All treatment plans were recalculated using Monte Carlo in order to produce dose and LET distributions. Clinical treatment plans were extracted from the Eclipse treatment planning system (v9.0) in DICOM format and then used as input for an in house Monte Carlo system. The system, called MC,\textsuperscript{1} uses the DICOM files to generate geometry specifications and other files describing the beam arrangement and delivery parameters. The files are then used as input for simulation with the Monte Carlo code MCNPX, as has been described previously.\textsuperscript{29,30} The Monte Carlo code used a

![Example imaging and treatment information for one patient can be seen in Fig. 1.](image_url)

**Fig. 1.** An example of the scans acquired at each timepoint (the CT, dose and linear energy transfer (LET) is only acquired at baseline) for patient 6. (a) sagittal T1-weighted MRI, (b) T2-weighted MRI, (c) fractional anisotropy (FA) map, (d) baseline CT with corresponding brain, CTV receiving 24 Gy (purple) and CTV boost (of 16 Gy, in blue) delineations, (e) dose distribution, and (f) LET for that plan.
simulated number of particles that ensured an acceptable uncertainty (±2%) of the dose distribution.

Physical doses per beam were summed to create a single dose distribution per patient and per voxel (for all beams in multi-phase plans). Similarly, per-beam LET maps were summed using the per-beam dose map as weighting factors, to create a single dose-weighted LET map per patient. Across the included patients the average dose per fraction was 1.73 Gy (1.6–1.8 Gy). Opposing beams or multiple beams equally spread out, with angles chosen individually for each patient, were used.

2.C. Image registration

The framework for image registration between time-points was a combination of rigid and deformable image registrations, designed to minimize the impact of patient positioning variations and anatomy changes over time and to be able to include multiple scans as required to assess the biological effect of radiation on a voxel-by-voxel basis. We used a previously published multi-modality image registration algorithm.31,32 At each timepoint, separately for each patient, all scans acquired were rigidly registered within each timepoint to create a timepoint “template” of all included modalities. The rigid registration used the scan with the highest resolution in each template as the reference, which in our study was the T2 MRI. Between each follow-up and corresponding baseline templates, a deformable image registration was carried out. This registration was iterative between all scans in each template, i.e. each individual scan in the moving template was deformably registered to all the scans of the fixed template, iteratively updating the combined template registration matrix for each combination. This process was repeated until convergence of the combined template registration matrix was reached. As the CT scan was included in the baseline template for each patient, dose and LET were thus also mapped for each voxel. The result was a dataset of imaging intensities relative to baseline, dose and LET on a voxel-by-voxel basis for each follow-up. The voxel-size in the templates was 1 × 1 × 1 mm³. An overview of the registration process can be seen in Fig. 2.

2.D. Data processing

Processing of the imaging signal was done to reduce the amount of noise in each scan and to focus on relevant regions of interest for data analysis. Two masks were created, one for FA MRI scans and one for T1/T2 weighted MRI scans. Both masks were initially restricted to cover only the brain as outlined on the CT for treatment planning (see Fig. 1), and further requirements were specified for each of the masks. In the FA image, we isolated voxels where the baseline image showed a white matter tract signal, that is, where the FA scan value was above the noise level. Specifically, we used a gaussian fit to the lower values of the voxel value frequency histogram for baseline FA images on a per-patient basis to filter out noise (see Fig. S1). A two-sigma cut-off was chosen for noise removal in the FA mask. The FA mask was then restricted to only include voxels with a baseline FA value above this cut-off (described in Fig. S1) and additionally restricted to voxels receiving doses above 35 Gy. This latter criteria was used as it has previously been shown that low doses do not appear to elicit a dose-response signal on FA imaging.31 An additional explorative analysis used varying dose thresholds (5 and 20 Gy). The T1/T2 mask had the same requirement of 35 Gy, but no further signal restrictions. Masks were created based on the baseline scans but applied to follow-up data after registrations.

2.E. Data analysis

We analyzed the data using nested generalized linear mixed regression models to relate dose and LET to variation in image signal. This was done separately for the three MRI modalities, T1, T2 FLAIR and FA images. The general regression model was33:

\[
\text{Follow-up}_{i,j,n} = a \cdot \text{Baseline}_{i,n} + b \cdot f(\text{dose}_{i,n}) + c \cdot \text{LET}_{i,j,n} \cdot f(\text{dose}_{i,n}) + \alpha_{ij},
\]

where the \(i\)-subscript refers to an individual patient, while the \(j\)-subscript refers to the different follow-up sessions for that patient, and the \(n\)-subscript refers to a specific voxel for the patient. Follow-up and Baseline represent the image voxel values of the scans, \(f(\text{dose})\) represent a function of the dose for that voxel and LET the linear energy transfer. Note that this model is the same as:

\[
\text{Follow-up}_{i,j,n} = a \cdot \text{Baseline}_{i,n} + b \cdot f(\text{dose}_{i,n}) \cdot (1 + d \cdot \text{LET}_{i,n}) + \alpha_{ij},
\]

where \(d = c/b\). In other words, assuming LET = 0 for photons gives RBE = 1 + \(c/b\) \cdot LET. This is the form used for many pre-clinical studies, and one can therefore directly compare our results to published RBE models. To account for any potential non-linear effects of dose, we tested three different functional forms:

\[
\begin{align*}
\text{f}(\text{dose}_{i,n}) &= \text{dose}_{i,n} \\
\text{f}(\text{dose}_{i,n}) &= \ln(\text{dose}_{i,n}) \\
\text{f}(\text{dose}_{i,n}) &= \text{dose}^2_{i,n}
\end{align*}
\]

The \(\alpha_{ij}\) factor in Eq. (1) represents the random, mixed effects per patient and per follow-up session, accounting for heterogeneity of patients and scan sessions. Thus, the \(b\) and \(c\) indicate how much a change in image voxel value can be contributed to the dose or dose-LET interaction term, respectively; the model form corresponds a linear dependence of biological effect on LET. This model fully utilizes data from all patients and all time points in one fit.

The optimal model was subsequently determined by examining residuals for each model fit, but with preference to the linear model in close calls. Models for each modality—T1, T2 and FA—were fitted separately. The regression model with the optimal functional form for dose was used to predict image changes as a function of dose (spanning...
the dose range in 50 equal steps) with a fixed baseline voxel value (FA = 0.26, T1 = 396 and T2 = 411, chosen as representative normal values for each scanning modality), five different fixed LETs (LET = 0.9, 1.1, 1.5, 2.5 and 5 keV/µm) and 186 days to follow-up. To illustrate the impact of LET on imaging changes, we also compared predicted changes with varying LET values—but a constant dose—to the “normal variation” in each of the imaging modalities. To obtain the range of “normal variation”, we created a mask for each patient of normal appearing white matter (NAWM) on the baseline scans. This mask was based on the FA signal, using the noise cut-off described in the data processing, but further excluded the GTV delineation. Mean and standard deviations of voxel values across all patients were acquired as estimates for NAWM for each modality.

To assess the interpatient and intrapatient variation in dose and LET dependence over time, we conducted separate regressions for each follow-up session, i.e. using the adjusted model:

\[
\text{Follow-up}_{i,j,n} = a_{ij} \cdot \text{Baseline}_{i,n} + b_{ij} \cdot f(\text{dose}_{i,n}) + c_{ij} \cdot \text{LET}_{i,n} \cdot f(\text{dose}_{i,n}),
\]

which provides a separate estimate for the \(b\) and \(c\) parameters for each patient and follow-up session. For simplicity, we only fitted this using the functional dependence of dose that was found optimal in the general model.

All data analysis was conducted in R (version 3.6.0) and all image registration and data preparation were done in Matlab (version 9.6.0.1135713 (R2019a) Update 3).

3. RESULTS

A total of six patients were included between the ages of 6 and 17, who all received standard clinical proton therapy and four follow-up MRI sessions each. All patients were treated with passive scattering proton therapy. Further details on the patient treatment can be seen in Table 1.

Patient 1 received MRI scans not adhering to the study protocol and was thus excluded from the analysis. Of the
remaining five patients, there were issues with ten follow-up sessions. Seven had to be excluded due to missing data, and for three others the standard registration pathway failed and the T2 sequence had to be excluded or replaced from the analysis. An overview can be seen in Table II. An example of our image registrations can be seen in Fig. 3.

The linear function of dose \( f(dose) = dose \) was selected based on simplicity as minimal difference was observed in residual analysis. Figure 3 show predictions of image changes as a function of dose and LET. This figure also shows our averaged NAWM values for each modality. We see a decrease in FA signal as a function of dose for all the investigated LET values. However, the signal increases as a function of LET, contrary to expectation, but all predictions are within the NAWM band. The T1 predictions appear relatively constant as a function of dose and LET, except for the very high-LET region. The T2 predictions show the largest dependence on both dose and LET, but with opposite effects; as the dose increases so does the T2 signal, but a higher LET value leads to a lower T2 signal.

In Table III, the parameters \( a, b \) and \( c \) are shown for each modality. All three modalities show a relevant dose dependence through the \( b \) parameter as \( b \) is of the order of a change in voxel value. The \( c \) parameter is a factor 10 lower, compared to the \( b \) parameter, for FA and T1, while of the same order for the T2 model. This indicates the dose^4LET-term is less impactful when predicting imaging changes as compared to the dose-term for FA and T1.

We additionally predicted voxel value change for various LET values and a fixed dose to the voxel of 35 Gy for FA and T2, as seen in Fig. 4. For the T2 image, a continuous decrease in signal was seen and this signal was different from NAWM for \( LET \geq 5.5 \text{ keV/\mu m} \). We investigated the predictions shown in Table III, Figs. 4 and 5 with different dose thresholds (5 and 20 Gy) with slightly varying results, see the summary in the supplementary material and Figs. S2–S5 and Tables S1 and S2.

The fit parameters \( b \) and \( c \) from Eq. (3) for individual follow-up sessions can be seen in Fig. 6. Here, points below the zero line indicate a decrease in voxel value over time, and points above indicate an increase over time. The y-axis is scaled to facilitate comparison between \( b \) and \( c \). The limits on the y-axis are found as the minimal and maximal value of \( b \) and \( c \) after they have been multiplied by the (median dose) and (median dose^4median LET) respectively. This way, the y-scale becomes a reflection of the median change in FU value compared to baseline that arises due to the (dose)- and (dose^4LET)-term in the voxels. This normalization is done internally for each modality. Intra patient variations seemed small compared to inter-patient variations for all modalities as seen by the grouping internally for each patient among the same parameter value. The b-values are negative for the FA image indicating the expected decrease in FA as function of...
dose. The $c$-values appear inconclusive and mostly smaller compared to the variations of the $b$-values, indicating that this dose+$LET$ term did not have as great an impact on imaging changes as the dose. No clear conclusions or consistency could be seen in the T1 image, which was a general trend across all analysis made in this study.

### 4. DISCUSSION

Three-dimensional imaging assays of radiation damage are promising to derive human tissue specific biological effects of radiation as function of dose and LET. The 3D in vivo assay allows sampling across multiple dose levels and LET values in the same patient, thus avoiding the need to accrue large numbers of patients to observe the signal from dose and LET over the random variation across patients. Continuous predictors typically also have much more statistical power than a binary time-to-event endpoint of clinical manifest toxicity.

On the downside, longitudinal imaging studies are hard to analyze in terms of image registration and in terms of statistical analysis of the high dimensionality data. Here we have tried to tackle those two problems by providing a framework for using longitudinal deformable image registrations and voxel-based statistical analysis, accounting for nesting of data on patient and follow-up session level, to assess the effect of dose and LET on the image assays across several patients and time points in each patient. Unfortunately, the number of patients accrued in our project is too small to draw firm conclusions. However, the expected dose response is derived on FA maps and we do provide means to assess the importance of LET compared to dose and interpatient variation. We observe substantial patient to patient variation in the internal model fits (i.e. sensitivity to dose and LET); in other words, inter-patient variation in radiation sensitivity may be a stronger factor than variation in biological effect across clinical proton beams.

A handful of previous publications have examined the use of imaging changes as markers for radiation damage to assess biological effectiveness of proton beam irradiation as function of dose and LET. In particular, two recent papers...
reported on radiation-induced brain lesions in adult patients, and related the presence of imaging changes to dose and LET on a voxel-by-voxel basis.\textsuperscript{38,39} The paper by Bahn et al demonstrated a relationship between imaging changes and LET in 110 patients treated for low-grade glioma, while Niemierko et al. were unable to find a LET dependence of necrotic changes in fifty patients treated for head and neck, skull base, or intracranial tumors. Conversely, they concluded that inter-patient variability in radio sensitivity was likely to overshadow any LET effect; much in line with our present findings. Of note, neither of the two studies used deformable image registration or assessed imaging changes as continuous measures.

We have deliberately chosen a formal statistical methodology testing the effect of dose and LET\textsuperscript{*}dose using conventional statistical methods rather than some of the widely available models of RBE rooted in mechanistic or in vitro modeling. The use of the pure statistical method here should ideally be compared to mechanistic modeling in larger series, but in terms of advantages the current method

---

**FIG. 4.** The predictions of model 1 (linear dose dependence), pooled over all patient and follow-up scan values as a function of dose for LET = [0.9, 1.1, 1.5, 2.5, 5.0] keV/µm. The y-axis is defined such that a decrease here over time represents a lower voxel value in the follow-up scans as compared to baseline. This prediction assumes a representative voxel value of the baseline scan across all patients. The prediction is what is expected to happen for a theoretical patient at a follow-up after 186 days. The top figure shows the predicted values for fractional anisotropy (FA) MRI, the middle for T1-weighted MRI and the bottom figure is for T2-weighted MRI scan values.
avoids the need to combine LQ modeling with RBE using formulas which may be stretched beyond clinical utility when applied to human tissue. Note, however, that our relatively simple functional form is equivalent to the linear dependence of RBE on LET used for a number of models based on pre-clinical data: \( \text{RBE} = 1 + K \cdot \text{LET} \) (where \( K = \frac{c}{b} \) for the current model). The ratio between the \( c \) and \( b \) parameters reported here thus provides an estimate of the dependence of the relative biological effectiveness on LET. Comparison using the methods proposed here

---

**Fig. 5.** The predicted image response as a function of LET for a constant dose (35 Gy).

**Fig. 6.** Fit parameters \( b \) and \( c \) to model (1), modelling the effect of dose and dose*LET, respectively (LET, linear energy transfer). These parameters are shown for all patients and all follow-ups as a function of days since baseline scan and for fractional anisotropy (FA) (top row), T1-weighted MRI (middle row) and T2-weighted MRI (bottom row) scans. To the right of each subplot, the \( b \) and \( c \) parameters are shown with error bars (one standard deviation) from five individual patient models; one for each patient including all follow-up data from that patient. The range of the y-axis has been adjusted to an equal range between all plots in terms of impact on the follow-up scan value in Eq. (3).
could hopefully shed light on the question of the modifying effect of LET on the dose in proton therapy in future series. Other weaknesses in our data analysis include not taking fraction size effects into account, averaging dose and LET over multi-phase treatments for some patients, and assuming independence of the radiation response for adjacent voxels.

In this study, we rely heavily on imaging data and changes to measure a response, but many of the patients included in the study did not exhibit significant image changes during our follow-up period. This could explain the diverging results. Also, the correlation between image changes and clinically meaningful endpoints is often weak and the functional form not well established. For example, our choice of FA signal as imaging marker has been questioned since protocol initiation: A study from 2019\textsuperscript{40} showed an increase in FA signal due to radiation damage and it was hypothesized that this increase was driven by an overall reduction in mean diffusivity. Another study\textsuperscript{41} showed that different white matter tracts are differently susceptible to radiation damage, with some tracts remaining unchanged, some showing an increase in FA signal, and some showing a decrease in FA signal. Additionally, the T1/T2 masks used in this study are very general and include both white matter, grey matter and organs at risk, all of which can have very different responses to radiation that cannot be captured by our model. This points to a potential critical weakness in the imaging assays: If the imaging marker is a composite signal of unspecified changes due to radiation, it may fail to provide guidance to the relative effect of radiation as function of LET. However, given a sufficiently strong imaging marker, our framework can enable in vivo studies of LET effects from radiation for specific tissues and/or regions. One could investigate specific structures, such as the brain ventricles, and create radiobiological models that account for intrapatient variations through our proposed regression analysis. We strongly suggest selecting imaging biomarkers which has been associated with a relevant clinical outcome. This framework should also be extended to include neighboring-voxel effects\textsuperscript{42} to improve accuracy of the models.

The deformable registration part of the framework can be applied to almost any follow-up analysis without the need to fine-tune the algorithm. It uses standard values for the deformable registrations and is thus generalizable to other datasets from other centers. Although there are no requirements on the resolution of the included scans, to compare the results across multi-center datasets, we recommend using standardized protocols to avoid inconsistencies and inhomogeneities.

5. CONCLUSIONS

We have demonstrated a framework for voxel-based registration and phenomenological fitting of longitudinal image data vs dose and LET to derive estimates of the biological effect of high LET radiation. This framework is available online.\textsuperscript{42}
