**Abstract**

**Motivation:** Trajectory inference (TI) for single cell RNA sequencing (scRNAseq) data is a powerful approach to interpret dynamic cellular processes such as cell cycle and development. Still, however, accurate inference of trajectory is challenging. Recent development of RNA velocity provides an approach to visualize cell state transition without relying on prior knowledge.

**Results:** To perform TI and group cells based on RNA velocity we developed VeTra. By applying cosine similarity and merging weakly connected components, VeTra identifies cell groups from the direction of cell transition. Besides, VeTra suggests key regulators from the inferred trajectory. VeTra is a useful tool for TI and subsequent analysis.

**Availability and implementation:** The Vetra is available at https://github.com/wgzgithub/VeTra.

**Contact:** kyoung.won@bric.ku.dk or junil.kim@bric.ku.dk

**Supplementary information:** Supplementary data are available at *Bioinformatics* online.

**1 Introduction**

Trajectory analysis using single cell transcriptomics is useful to understand temporal transition of cell states. By showing transcriptional changes along the obtained trajectory (or pseudo-time), Trajectory inference (TI) has been applied to studying various biological processes including cell cycle, cancer development and cell differentiation (Tran and Bader, 2020).

Besides pseudo-temporal analysis, TI has been used to assist identifying gene regulatory rules. Visual inspection of gene expression changes along the inferred trajectory suggested potential regulators for the biological processes (Trapnell et al., 2014). Systemic approaches have been developed to reconstruct gene regulatory networks (GRNs) using the gene expression changes along the inferred trajectory (Kim et al., 2021; Matsumoto et al., 2017). Well inferred trajectory helped improve the performance of GRN reconstruction (Qiu et al., 2020).

At present, more than 70 methods have been published to infer trajectory from scRNAseq data (Saelens et al., 2019). Majority of TI approaches have been developed based on the transcriptomic similarity among cells. Pseudo-time is obtained from the ordered cells based on the transcriptomic similarities (Saelens et al., 2019). However, transcriptomic similarity cannot specify the initial and the terminal points of the trajectory. When using TI algorithms based on the transcriptomic similarity, a user has to provide the direction of a cellular process, roots/terminals using the marker genes or any prior knowledge about experiments to obtain pseudo-time (Haghverdi et al., 2016; Setty et al., 2016; Trapnell et al., 2014).

It is more challenging to infer trajectory when cell dynamics are complex. It is difficult to assign an accurate fate (lineage) to a cell around branching regions. To improve robustness in detecting TI, there have been attempts to confine the inferred trajectory to a set of fixed topological structures, e.g. linear, bifurcation and cycle (Saelens et al., 2019). However, the use of pre-defined structures can restrict the opportunity to identify new structures.

Recently, RNA velocity has been suggested to analyze scRNAseq data by incorporating mRNA dynamics (La Manno et al., 2018). Notably, RNA velocity can provide the direction and the speed of movement of individual cells and visualize the dynamic cell transitions without any prior knowledge. The direction information from RNA velocity provides a potential solution to determine the developmental trajectory of a cell around branching points. Therefore, RNA velocity can be useful in developing precise TI tools.

To obtain precise TI and subsequent analysis without prior information, we developed VeTra. VeTra identifies cell groups belonging to the same lineage and suggests potential regulators in the identified groups. Compared with previous undirected graph based methods such as minimum spanning tree (Street et al., 2018) and graph-partitioning algorithm (Wolf et al., 2019), VeTra builds directed graph...
from RNA velocity. VeTra identifies isolated cell transition paths by searching for weakly connected components (WCC) which represent the coarse-grained structure of connected community (An et al., 2004). The isolated paths are further grouped together using the hierarchical clustering algorithm to finally form potential development lineages. As the results, VeTra identifies cell transition trajectory and determines the memberships of cells to each trajectory even around branching points. VeTra further suggests key regulators along each trajectory by integrating the engine of TENET (Kim et al., 2021). VeTra is a user-friendly tool for TI and subsequent analysis.

2 Materials and methods

2.1 VeTra groups the cells belonging to the same stream of trajectory

VeTra is an RNA velocity based TI tool that enables accurate lineage tracing and subsequent analysis for gene regulation. VeTra performs lineage tracing from the root to the terminal states by grouping cells based on the similarity in direction of cell transition. This enables VeTra to perform TI without prior knowledge or predefined lineage topology.

VeTra reconstructs the pseudo-temporal order of cells based on the coordinates and the velocity vector of cells in the low-dimensional embedding. The velocity vectors are estimated by extrapolating the spliced/unspliced read ratio to the local neighboring cells (La Manno et al., 2018). Given velocity vectors (Fig. 1A), VeTra reconstructs multiple directed graphs. To link cells based on transition, k nearest neighbors of a cell with similar direction are selected using cosine similarity (cos 1) (Fig. 1B, Section 2). Among them, the nearest cell located upstream with the highest cosine similarity (cos 2) is selected (Fig. 1B, Section 2). Once all cells were investigated for their next transition, multiple directed graphs are obtained (Fig. 1C). To find a coarse-grained structure of the directed graph, VeTra identifies WCCs where every cell is reachable from every other cell regardless of the direction of relationships (Steven, 1990) (Fig. 1D). The WCCs are grouped together when they are similar and close each other (Section 2, Fig. 1E).

Finally, we obtained the pseudo-time ordering of cell groups (Fig. 1F) by projecting the member cells onto the principal curve (Hastie and Stuetzle, 1989).

2.2 VeTra’s trajectory matches well with the known lineage or biological process

We applied VeTra to infer the trajectory for various scRNAseq datasets with known cell dynamics structures for pancreatic development (Bastidas-Ponce et al., 2019; Bergen et al., 2020), chromaffin cell differentiation (Furlan et al., 2017; La Manno et al., 2018), neural lineages in the hippocampus (Hochgerner et al., 2018; La Manno et al., 2018) and cell cycle (Xia et al., 2019). For benchmarking we used Slingshot (Street et al., 2018), FateID (Herman and Grün, 2018) and PAGA (Wolf et al., 2019) since they showed best performance in recent benchmarking tests (Sadens et al., 2019). We also include CellRank (Bergen et al., 2020) and CellPath (Zhang and Zhang, 2021) as they are developed based on RNA velocity. We used Diffusion pseudo-time (DPT) to provide pseudo-time ordering to CellRank. We provided known roots and terminals cells to run Slingshot and FateID.

2.2.1 Pancreatic development (a topology with crossing branches)

During the pancreatic development endocrine progenitors differentiate into alpha or beta cells (Bastidas-Ponce et al., 2019). Ductal cells are originated from common progenitors, which are fated to endocrine and exocrine lineages (Reichert and Rustgi, 2011). From the transcriptome of pancreatic development (E15.5), VeTra identified three major trajectory groups: (i) alpha cell differentiation from endocrine progenitors (EP), (ii) beta/epsilon differentiation from EP and (iii) ductal development (Fig. 2A). The first two clusters were commonly originated from EPs and bifurcated into different lineages.

CellRank identified similar three trajectories with a slightly different starting point close to ductal cells for alpha and beta cell trajectories (Fig. 2A). FateID identified the trajectory to alpha and beta cells but failed in identifying ductal lineage. Slingshot did not find delta/beta cell lineage as well as ductal cell lineage (Fig. 2A). PAGA inferred coarse-grained trajectories from EP to alpha, beta, delta and epsilon cells but it also found trajectories between unrelated cell types (e.g. between alpha and beta cells) (Supplementary Fig. S1). CellPath did not find the path to ductal cells (Supplementary Fig. S2B).

2.2.2 Chromaffin cell development (a topology with diverging branches)

During the development, the chromaffin cells and sympathoblasts cells are generated from Schwann cell precursors (SCPs) (Furlan et al., 2017). VeTra, FateID and Slingshot successfully captured the
branches toward sympathoblasts and chromaffin cells (Fig. 2B).
CellRank identified SCPs as initial states but failed to identify proper
terminal states (Fig. 2B). PAGA connected bridging cells presumably
falsely as their fates are already committed to each branch (based on
RNA velocity) (Supplementary Fig. S1). CellPath only identified the
path to the chromaffin cells (Supplementary Fig. S2C).

2.2.3 Cell cycle (a cycling topology)
We applied TI tools on the scRNAseq dataset from U-2 OS cells
(Xia et al., 2019) and investigate the topology for cell cycle. VeTra
identified a single circular trajectory, starting at G1 phase toward
G1/S, G2/M and M phase, and finally going back to G1 phase (Fig. 2C).
Given the root cells in G1 phase, Slingshot identified similar-
trajectory. On the other hand, CellRank and CellPath estimated
a linear-like trajectory (Fig. 2C, Supplementary Fig. S2D). PAGA
connected cell populations with cycle, but inferred wrong trajec-
tries between separated cell cycles (Supplementary Fig. S1).

2.2.4 Hippocampus development (complex diverging branches)
We further evaluated the performance using the scRNAseq data for
hippocampus development, which has been identified to have five
diverging branches: astrocytes, oligodendrocyte progenitor cells
(OPC), dentate gyrus granule neurons and pyramidal neurons
including CA1, CA2, CA3 and subiculum (La Manno et al., 2018).
Among these five main branches, astrocytes and OPCs are commonly
branched from radial glial cells and the other neuronal branch
cells are originated from immature neuroblast cells (La Manno
et al., 2018).

VeTra identified five lineages toward CA1-subiculum, CA2-3-4,
granule, astrocyte, OPC (Fig. 2D). VeTra also predicted that CA2-
3-4 cells and granules share the same neuroblastic origin (NbH1) and
astrocytes and oligodendrocyte progenitors share the same inter-
mediate progenitor origin (nNPC), which is consistent with the ori-
ignal RNA velocity results (La Manno et al., 2018). CellRank
identified one correct (NbH1) and two incorrect (Granule, and CA1-
Sub) initial states (Fig. 2D). The five terminal states estimated by
CellRank were CA, CA2-3-4, ImmAstro, GliaProg and nNPC, includ-
ing three potential misclassified intermediate states (GliaProg, nIPC
and CA). Due to potential incorrect initial and terminal state assign-
ment, the trajectory inferred by CellRank failed in distinguishing the
five separated trajectories. Slingshot detected five lineages (Fig. 2D)
but determined wrong initial states (always from ImmAstro). FateID
did not infer any meaningful trajectories (Fig. 2D). PAGA inferred
clear trajectories from NbH1 to CA1-sub, CA2-3-4 and Granule.
However, PAGA falsely connected ImmAstro and GliaProg
(Supplementary Fig. S1). CellPath showed severely truncated paths
for this dataset (Supplementary Fig. S2A).

2.3 Performance evaluation using simulated datasets
The assessment using scRNAseq data demonstrated the outstanding
performance of VeTra. However, the gold standard annotation for
individual cells is usually not provided and it is hard to quantify the
performance. For quantitative assessment, we simulated scRNAseq
datasets using Dyngen (Cannoodt et al., 2020) and generated three
lineage structures: binary tree, trifurcation and converging. We add-
itionally included a disconnected structure from VeloSim (Zhang
and Zhang, 2021a,b). Beside visualization, we calculated the matching-
score by obtaining the average value of the normalized hamming
distances (D) between the predicted and the known lineages. We
used (1 − D) × 100 as the score.
VeTra successfully identified the identified lineages for four simulated
datasets. Slingshot identified successfully except for the disconnected path. However, other approaches were not successful
compared with VeTra or Slingshot (Supplementary Fig. S3). The
overall comparison (Supplementary Table S1) demonstrates the ro-
busness of VeTra in TI.

2.4 VeTra provides condition-specific master regulator
It has been studied that TI can influence the performance of GRN
reconstruction. VeTra is equipped with a function to suggest key
regulators by adopting the engine of TENET (Kim et al., 2021) that
we previously developed to reconstruct GRN. TENET has a func-
tion to identify key regulators from the inferred causal relationships
with their target genes (Kim et al., 2021). Incorporating TENET,
VeTra has a function to identify most influential transcription fac-
tors (TFs) for the inferred trajectory.
Using the RNAseq dataset from pancreas development (Bastidas-
Ponce et al., 2019), VeTra found key regulators for the three pre-
dicted major branches: alpha, beta and ductal (Fig. 3A). The key
predicted regulators that distinguishing alpha cell development
against others were Pax6, and Arx. Pax6 and Arx have been known
to have a role during alpha cell development (Ashery-Padan et al.,
2004; Gosmain et al., 2011). Pax6 regulates genes related to gluca-
son production (Ashery-Padan et al., 2004). Arx has been shown to
play a similar role in alpha-cell development (Gosmain et al., 2011).
VeTra also identified Neurog3 an endocrine (alpha and beta) specif-
icaly key regulator (Gradwohl et al., 2000; Gu et al., 2002; Schwitzgebel et al., 2000).

In addition, VeTra revealed condition-specific regulators for the
five lineages of hippocampus development (Fig. 3B). For instance,
Nrl4a3 (Nor-1) is predicted a CA2-3-4 specific regulator by VeTra.
Nor-1 deficient mice appear to have abnormal pyramidal cell layer
in CA1 to CA3 (Ponnio and Conneely, 2004).

3 Algorithm
To pick the most appropriate cell to which the vector of the cell i
is pointing, & closest neighbor cells are collected from the head of
the vector of a cell i in the low-dimensional space (Fig. 1B). Among
the neighbor cells, cells with similar direction are selected using a cosine
similarity criterion between the cell i and the neighbor cell j (cosij =
\frac{\sum_i v_i \overline{v_j}}{|v_i||\overline{v_j}|} > 0.5) (Fig. 1B, where \overline{v_i} and \overline{v_j} denote velocity vectors (2D
coordinates) of cell i and cell j. The cell with the highest similarity
for cosij = \frac{\sum_i v_i \overline{v_j}}{|v_i||\overline{v_j}|} where \overline{v_i} is the vector from v_i to v_j located up-
stream of the cell i is finally selected to obtain a directed graph in
the same stream of trajectory (Fig. 1B).
The hierarchical clustering is applied to the WCCs for further grouping (Fig. 1E). The distance between the two sub-graphs is defined by the maximum distance of all the closest pairs of cells. To calculate the distance between cells, we calculated the Euclidean distance in the four-dimensional space (two dimensions using the gene expression and the other two using the velocity vector in the reduced dimensional space). To obtain full trajectory (from the root to the branch), we extended the memberships if a cell located nearby is similar ($\cos_{ij} > 0.7$). We obtained the pseudo-time ordering by projecting the member cells onto the principal curve (Hastie and Stuetzle, 1989).

4 Discussion

TI is a widely used approach to understand temporal dynamics of cells from scRNAseq data. A number of approaches have already been developed to infer the trajectories. As shown in the examples using the simulated as well as real scRNAseq data (Fig. 2 and Supplementary Figs S1–S3), however, there is still room for algorithmic improvement for accurate detection of trajectory. We have noticed that the results of current TI tools do not always match with the cell dynamics observed by RNA velocity (La Manno et al., 2018). RNA velocity, by providing the direction of cell transition, enabled visual inspection of cell trajectory. VeTra is designed to group cells in accordance with the cell transition drawn by RNA velocity. To fully use the vector space provided by RNA velocity, VeTra used cosine similarity and obtained cell groups. The use of cosine similarity makes VeTra rely on the vector space for TI.

Our benchmarking test on the scRNAseq datasets exemplifies that VeTra successfully identified the trajectory drawn by RNA velocity and produced reasonable results that matched with the known topological structures for cell development and biological processes. It is interesting that VeTra outperformed other RNA velocity based methods such as CellRank (Bergen et al., 2020) and CellPath (Zhang and Zhang, 2021a,b) in our tests. Instead of using RNA velocity directly, CellRank calculates the probabilities of each cell transition to all terminals from initials. Therefore, the terminal states are not deterministic for CellRank. This may have influenced the performance of CellRank. CellPath uses meta-cells to obtain smoothed RNA velocity and reduce the computing cost (Zhang and Zhang, 2021a,b). In our test, CellPath has failed to annotate large number of cells for each lineage. A meta-cell is a cluster of cells. We suspect that meta-cells may smooth cell direction too much when cells exhibit diverse direction. Compared with them, VeTra tried to follow the velocity vector using cosine similarity without further processing them.

As the results, VeTra relies on RNA velocity calculation. RNA velocity can heavily depend on the correct measurement of spliced and unspliced RNA abundance. A recent study showed that the choice of experimental setting can change the results of RNA velocity (Soneson et al., 2021). As a downstream analysis tool of RNA velocity, VeTra can use the output from Velocyto (La Manno et al., 2018) or scVelo (Bergen et al., 2020). A previous study shows that the results of Velocyto and scVelo can be different (Cannoodt et al., 2020), which can also cause different results for VeTra. We investigated VeTra’s output after running Velocyto and scVelo. For the cell cycle and chromaffin development datasets, both Velocyto and scVelo showed similar results. However, we found different results for the hippocampus and the pancreas development datasets (Supplementary Fig. S4). For VeTra, CellRank and CellPath, we selected the RNA velocity approach that produces the better performance for each dataset.

VeTra is equipped with the tool to predict key regulators by adopting the gear of TENET, a GRN reconstructor based on TE. It was discussed previously that TENET is capable of detecting key regulators using the aligned scRNAseq (Kim et al., 2021). VeTra equipped with the TENET engine will be useful for downstream analysis of TI.

VeTra requires the 2D coordinates embedded from expression profile and the RNA velocity vectors for each cell. A user can specify the number of groups. The output files include (i) 2D embedding figures colored by grouping of cells, (ii) 2D embedding figures colored by pseudo-time ordering, (iii) lists of selected cells for each group and (iv) the pseudo-time ordering information for each group.
