Abstract

We introduce a dense and a dilute loop model on causal dynamical triangulations. Both models are characterised by a geometric coupling constant $g$ and a loop parameter $\alpha$ in such a way that the purely geometric causal triangulation model is recovered for $\alpha = 1$. We show that the dense loop model can be mapped to a solvable planar tree model, whose partition function we compute explicitly and use to determine the critical behaviour of the loop model. The dilute loop model can likewise be mapped to a planar tree model; however, a closed-form expression for the corresponding partition function is not obtainable using the standard methods employed in the dense case. Instead, we derive bounds on the critical coupling $g_c$ and apply transfer matrix techniques to examine the critical behaviour for $\alpha$ small.
1 Introduction

If a two-dimensional statistical mechanical model with a second-order phase transition is coupled to a random background, its critical exponents may change and there may be a back-reaction on the background geometry changing its Hausdorff dimension. A prominent example of this phenomenon is the Ising model on a random two-dimensional triangulation (or quadrangulation), as demonstrated in [1]. Other examples are dimer models [2], Potts models [3, 4], and multicritical models [5], see also [6] for an overview. The relation between the critical exponents, or scaling dimensions, of a matter field on a flat background and on a random curved background is given quite generally by the KPZ-formula of Liouville quantum gravity [7]. A conjectured formula for the Hausdorff dimension of the background geometry as a function of the central charge of the matter fields can be found in [8], although recent mathematical results in Liouville quantum gravity [9, 10] imply restrictions on the possible range of validity of this formula.

It is natural to ask how universal this so-called dressing of critical exponents is with respect to the ensembles of background geometries considered. In particular, it is natural to compare the ensemble of unrestricted dynamical triangulations (DT) (see e.g. [6]) considered in the references above, with the ensemble of causal dynamical triangulations (CDT) [11]. Without coupling to a matter system, these ensembles, which we shall call pure DT and pure CDT in the following, exhibit different critical behaviours, the former having Hausdorff dimension 4 [12, 13], while the latter has Hausdorff dimension 2 [14]. Very few analytical results are available concerning matter systems coupled to CDT. A number of numerical studies have been carried out, notably for Ising type and Potts type models [15, 16, 17], but there is no clear indication of a change in the critical exponents. In [18, 19], a class of restricted dimer models are mapped to certain labelled tree models. Using this, the corresponding Hausdorff dimension is found to be affected by the dimer system, although the underlying mechanism remains unclear. In the
work [20], a class of CDT models with curvature-dependent weights are found to exhibit the same scaling behaviour as pure CDT.

In statistical mechanics, one usually works with local degrees of freedom, such as spins or heights, as in the Ising and Potts models above. However, percolation and polymer systems, for example, require that one keeps track of connectivities or some other inherently nonlocal degrees of freedom, and this shift in paradigm has a profound effect on the physical properties of the models. Critical fully-packed loop models on regular square lattices have thus been found to give rise to logarithmic conformal field theories in the continuum scaling limit [21]. Using underlying Temperley-Lieb algebraic structures [22, 23], these loop models are found to be Yang-Baxter integrable and amenable to exact solutions. One of these models describes critical dense polymers and has been solved exactly on the strip [24], the cylinder [25] and the torus [26], confirming predictions about scaling dimensions made in [27, 28, 29]. Other types of loop models have also been constructed, including dilute loop models associated with the O(n) models [30, 31] where the configurations may contain spaces of variable sizes in between the loop segments. Loop models have also been coupled to random surfaces [5, 32], including random triangulations [33, 34]. However, to the best of our knowledge, loop models have yet to be coupled to CDT.

In this paper, we introduce and study two models of loop configurations on two-dimensional causal dynamical triangulations: a dense loop model and a dilute loop model, reminiscent of the familiar fully-packed and dilute loop models, respectively. Both models are characterised by a geometric coupling constant $g$ associated with the underlying triangulations, as in pure CDT, and a loop parameter $\alpha$ that encodes the relative weights of the admissible loop configurations on individual elementary triangles. No weight is associated with the number of loops in the models considered here, effectively setting the corresponding loop fugacities to 1. We show that the known correspondence between pure CDT and planar trees [35, 14] extends to each of the loop models and a corresponding class of labelled trees. This implies simple relations between the partition functions of the loop models and those of the associated labelled tree models. In the case of the dense loop model, we solve the corresponding tree model exactly and find that its Hausdorff dimension equals that of pure CDT. The critical behaviour of the loop model is readily extracted from the closed-form expression we obtain for the partition function following our tree analysis. Although the dilute model can likewise be mapped to a planar tree model, a closed-form expression for the corresponding partition function is not obtainable using the techniques employed in the dense case. Instead, we apply a transfer matrix formalism and use analyticity arguments to examine the critical behaviour of the loop model for $\alpha$ close to 0. We conclude that the critical behaviour for $\alpha$ small is different from that of pure CDT, and provide an explanation for this difference. Based on results in [36], we argue that the Hausdorff dimension equals 1 in this phase. While it is possible that these results hold for more general values of $\alpha$, our analysis has not been able to confirm this. In fact, it is consistent with our findings that there exists a transition point $\alpha_0 \in (0, 1)$ at which the scaling behaviour changes.

This paper is organised as follows. In Section 2, we introduce the dense and dilute loop models and define the associated partition functions. In Section 3, for each of the loop models, we establish a correspondence between the set of allowed loop configurations and a set of labelled planar trees. The critical properties of the labelled tree models are investigated in Section 4. In Section 5, we use the tree results to obtain an explicit expression for the dense loop model partition function from which we determine the critical behaviour of the model. In our analysis of the dilute loop model, we supplement the relevant tree results with insight obtained using a transfer matrix formalism to establish a relation between the critical coupling constant and the loop parameter $\alpha$. For $\alpha$ small, we determine the critical behaviour of the partition function and identify two possible scenarios for larger values of $\alpha$. Finally, Section 6 contains some concluding remarks, including a brief discussion of possible future research directions.
2 Loop models

Before defining the loop models in Sections 2.2 and 2.3, we recall properties of causal dynamical triangulations in Section 2.1. There and in subsequent sections, we refer to two-dimensional causal dynamical triangulations simply as causal triangulations. We also adopt the convention that \( \mathbb{N} \) and \( \mathbb{N}_0 \) denote the set of positive integers and non-negative integers, respectively.

2.1 Causal triangulations

A causal triangulation of a disk is defined by a central vertex \( x \) and a sequence of cycles (circular graphs) \( S_0 \equiv \{x\}, S_1, \ldots, S_m \), where \( m \) is the height, such that, for each \( k = 0, 1, \ldots, m - 1 \), the annulus \( A_k \), bounded by \( S_k \) and \( S_{k+1} \), is triangulated. Note that \( A_0 \) is merely the disk with boundary \( S_1 \) and vertex \( x \) at its centre. As illustrated in Figure 1a, each elementary triangle within \( A_k \), \( k = 1, \ldots, m - 1 \), is either forward-directed, i.e. has one edge in \( S_k \) and the opposite vertex in \( S_{k+1} \), or backward-directed, i.e. has one edge in \( S_{k+1} \) and the opposite vertex in \( S_k \). Edges within a cycle are called space-like and are coloured red, while edges between neighbouring cycles are called time-like and are coloured black. The number of space-like edges in \( S_k \) is denoted by \( |S_k| \), where we note that \( |S_0| = 0 \) and \( |S_k| > 0 \) for \( k \geq 1 \).

A vertex \( v_1 \) in \( S_1 \), or equivalently the edge \( \{x, v_1\} \) (coloured orange in Figure 1a), is distinguished. From \( v_1 \), the rightmost outwardly emanating edge connects \( v_1 \) to a vertex \( v_2 \) in \( S_2 \). Likewise, \( v_2 \) is linked to a vertex \( v_3 \) in \( S_3 \) via its rightmost outwardly emanating edge. Continuing this procedure till we reach the outermost cycle \( S_m \) produces a sequence of vertices \( v_0 \equiv x, v_1, \ldots, v_m \), where each neighbour pair is connected by a time-like edge: \( \{v_k, v_{k+1}\} \), \( k = 0, \ldots, m - 1 \). Relative to the distinguished vertex \( v_k \), a clockwise order is assigned to the space-like edges in \( S_k \). Accordingly, the first (leftmost) triangle in the annulus \( A_k \), \( k = 1, \ldots, m - 1 \), is forward-directed. Note that one can apply the above prescription to construct a causal triangulation of a cylinder by omitting \( S_0 \) and letting \( S_1 \) correspond to the first instant of time.

Figure 1: (a) Causal triangulation of the disk, with distinguished edge \( \{x, v_1\} \). (b) Extension of the disk triangulation in the left figure to a triangulation of the sphere, the latter being obtained by identifying neighbouring dotted time-like edges, including the outer red nodes.
Let \( C_m(N) \) denote the set of causal disk triangulations of height \( m \) with \( N \) vertices, and similarly \( C_m \) the set without constraints on the number of vertices, and define

\[
|C| := \sum_{k=0}^{m} |S_k|, \quad C \in C_m.
\]

That is, \( |C| \) counts the number of space-like edges in \( C \) and equals the number of vertices in \( C \), excluding the central vertex. We find it convenient to include the degenerate case \( m = 0 \), where \( C \equiv S_0 \) and \( |C| = 0 \) for the unique ‘triangulation’ \( C \in C_0 \). The pure CDT partition functions are then defined as

\[
Z(g) := \sum_{m=0}^{\infty} Z_m(g), \quad Z_m(g) := \sum_{C \in C_m} g^{\mid C \mid}.
\]

(2.1)

It is well known [11], and will also be shown below, that there exists a critical coupling \( g_c > 0 \) such that \( Z(g) \) is finite and analytic for \( |g| < g_c \), while \( Z(g) \) is divergent for \( g > g_c \) and hence has a singularity at \( g = g_c \). We note that \( Z_0(g) = 1 \).

To provide a geometric interpretation in terms of triangulation area, it is convenient to extend the triangulated disk \( C \) to a triangulated sphere \( \bar{C} \) by adjoining forward-directed triangles to each space-like edge in \( S_m \), identifying the new time-like edges that are incident on the same vertex in \( S_m \). Such an extension is illustrated in Figure 1b. Note that the ‘outer’ vertices of the added triangles are all identified, suggesting the introduction of \( S_{m+1} \equiv \{y\} \), where \( y \) is the pole opposite to \( x \). In the degenerate case \( C \in C_0 \), we set \( \bar{C} \equiv C \) and accordingly have \( y = x \). We define the area \( a(\bar{C}) \) as the number of elementary triangles in \( \bar{C} \). Since \( a(\bar{C}) = 2|C| \), it follows that

\[
Z_m(g) = \sum_{C \in C_m} g^{a(\bar{C})/2}.
\]

2.2 Dense loop model

In the dense loop model, the set \( L_{de}^m(N) \) of allowed loop configurations of height \( m \) with \( N \) vertices is obtained from the set \( C_m(N) \) by replacing each elementary triangle in every configuration \( C \in C_m(N) \) with one of the two similarly directed triangles in Figure 2. These triangles are constructed by decorating the original empty triangles with blue arc(s). Arcs within elementary triangles are non-intersecting and defined up to regular isotopy, that is, they can be bent and stretched but cannot be cut. Loop segments may form (closed) loops but are only allowed to terminate on the boundary of the triangulation (the cycle \( S_m \)). This enforces a compatibility condition on shared space-like edges. The set of dense loop configurations of height \( m \), without constraints on the number of vertices, is denoted by \( L_{de}^m \). An example of a dense loop configuration is depicted in Figure 3a.

Each crossing of a space-like edge by a loop segment is called an intersection. We denote by \( s(L) \), respectively \( |L| \), the number of intersections and space-like edges in \( L \in L_{de}^m \), and define the partition functions for the dense loop model by

\[
Z_{de}(g, \alpha) := \sum_{m=0}^{\infty} Z_{de}^m(g, \alpha), \quad Z_{de}^m(g, \alpha) := \sum_{L \in L_{de}^m} g^{|L|}\alpha^{|L|.}
\]
Figure 3: (a) Dense loop configuration on a causal triangulation of the disk, with a distinguished edge incident to the central vertex. (b) Extension of the loop configuration in the left figure to a loop configuration on the triangulated sphere, the latter being obtained by identifying neighbouring dotted time-like edges, including the outer red nodes. With the given prescription for constructing the sphere, the extension of the loop configuration is unique.

Here $\alpha \in [0, 1]$, where we take $\alpha^n$ to mean $\delta_{n,0}$ for $\alpha = 0$ and $n \in \mathbb{N}_0$. Note that these partition functions reflect that the loop fugacity has been set equal to 1. It will be shown below that, for fixed $\alpha$, there exists $g_{c}^{de}(\alpha) > 0$ such that $Z_{de}(g, \alpha)$ is analytic as a function of $g$ for $|g| < g_{c}^{de}(\alpha)$, while it is divergent for $g > g_{c}^{de}(\alpha)$. We note that $Z_{0}^{de}(g, \alpha) = 1$.

As in the pure CDT model, we may extend the disk triangulations underlying the loop configurations to sphere triangulations (defined as in Section 2.1). Correspondingly, we may extend the loop configuration $L$ defined on the triangulated disk $C$ to a loop configuration $\tilde{L}$ on the triangulated sphere $\tilde{C}$. In fact, there exists a unique assignment of arcs to the additional forward-directed triangles in $\tilde{C}$; it is obtained by mirroring their backward-directed counterpart with which they share a space-like edge in $S_m$. Such an extension is illustrated in Figure 3b. As before, the area $a(\tilde{L})$ is defined as the number of elementary triangles in $\tilde{L}$, while we now also define the length $l(\tilde{L})$ of the loop configuration $\tilde{L}$ as the number of elementary arcs. Noting the relations $a(\tilde{L}) = 2|L|$ and $l(\tilde{L}) = a(\tilde{L}) + s(L)$, we may re-express the fixed-height partition function as

$$Z_{m}^{de}(g, \alpha) = \sum_{\tilde{L} \in \tilde{C}_{m}^{de}} g^{a(\tilde{L})/2} \alpha^{l(\tilde{L})-a(\tilde{L})}.$$

### 2.3 Dilute loop model

In the dilute loop model, the set $\mathcal{L}_{m}^{de}(N)$ of allowed loop configurations of height $m$ with $N$ vertices is obtained from the set $\mathcal{C}_{m}(N)$ by replacing each elementary triangle in every configuration $C \in \mathcal{C}_{m}(N)$ with one of the four similarly directed triangles in Figure 4. These triangles are constructed by decorating the original empty triangles with at most one blue arc. As in the dense loop model, an arc within an elementary triangle is defined up to regular isotopy, the crossing of a space-like edge by a loop segment is called an intersection, and loop segments may form (closed) loops but are only allowed to terminate.
on the boundary of the triangulation. Contrary to the dense loop model, a compatibility condition is thereby enforced on both types of shared edges: space-like as well as time-like. An example of a dilute loop configuration is depicted in Figure 5a. We let $\mathcal{L}^d_m$ denote the set of dilute loop configurations of height $m$, without constraints on the number of vertices. The partition functions for the dilute loop model (with loop fugacity 1) are then defined by

$$Z^d_m(g, \alpha) := \sum_{L \in \mathcal{L}^d_m} g^{|L|/2} \alpha^s(L),$$

where $s(L)$, respectively $|L|$, denotes the number of intersections and space-like edges in the loop configuration $L$. As in the dense case, $\alpha \in [0, 1]$, and it will be shown that, for fixed $\alpha$, there exists $g^d_c(\alpha) > 0$ such that $Z^d_g(g, \alpha)$ is analytic as a function of $g$ for $|g| < g^d_c(\alpha)$, while it is divergent for $g > g^d_c(\alpha)$. We note that $Z^d_0(g, \alpha) = 1$.

In both loop models, let $s_k(L)$ denote the number of intersections of $S_k$, where we observe that $s_0(L) = 0$. In the dilute loop model, the compatibility conditions along shared time-like edges, following from the requirement that loop segments can only terminate on the boundary, imply that the parity (even or odd) of $s_k(L)$ is the same for all $k$:

$$s_k(L) \equiv s_{k'}(L) \pmod{2}, \quad \forall k, k'.$$

Since the dilute loop configurations here are defined on disks (for which $s_0(L) = 0$), this parity is even. As an immediate consequence, we have

$$s(L) = \sum_{k=0}^m s_k(L) \in 2\mathbb{N}_0.$$
Figure 5: (a) Dilute loop configuration on a causal triangulation of the disk with a distinguished edge incident to the central vertex. (b) Extension of the loop configuration in the left figure to a loop configuration of the triangulated sphere, the latter being obtained by identifying neighbouring dotted time-like edges, including the outer red nodes. With the given prescription for constructing the sphere, there are two possible extensions of the loop configuration.

3 Tree correspondences

In this section, we develop correspondences between models defined on causal triangulations and models on planar trees. The partition functions of the matched constructions are closely related, facilitating the use of tree methods in the analysis of the CDT model partition functions.

3.1 Pure CDT model

Let $\mathcal{T}_m(N)$ denote the set of planar trees of height $m + 1$ with $N$ edges and a root of degree 1, and $\mathcal{T}_m$ the set of planar trees of height $m + 1$ and a root of degree 1. As noted in [35, 14], there exists a bijective correspondence

$$\psi: \mathcal{C}_m(N) \rightarrow \mathcal{T}_m(N).$$

To construct it, let $C \in \mathcal{C}_m(N)$. For each vertex in $S_k$, $1 \leq k < m$, remove the rightmost outward-pointing time-like edge, as well as all space-like edges, and add a new vertex $x_0$ and a corresponding edge $\{x, x_0\}$ immediately to the left (viewed outwardly) of the distinguished edge $\{x, v_1\}$. The resulting graph, $T = \psi(C)$, is a planar tree with root $x_0$ of degree 1, and the map $\psi$ is readily seen to be invertible. Note that the vertices of $C$ and $T$ are the same, except for the vertex $x_0$, and that the graph distance from $x$ to any vertex $v$ in $C$ and the one between the corresponding vertices in $T$ are the same. An example of the construction of $\psi(C)$ is given in Figure 6.

We introduce

$$V_k(T) := \{v \in T \mid d_T(x_0, v) = k + 1\}$$

as the set of vertices of $T \in \mathcal{T}_m$ with graph distance $k + 1$ from $x_0$, writing

$$V_k(T) = \{v_{k,i} \mid i = 1, \ldots, |V_k(T)|\},$$
where $v_{k,1} \equiv v_k$ is the distinguished vertex, defined in Section 2.1 and the remaining $v_{k,i}$ are labelled clockwise from $v_{k,1}$, with $i = 2, \ldots, |V_k(T)|$. We also define

$$V(T) := \bigcup_{k=1}^{m} V_k(T),$$

which is the vertex set of $T$, excluding the vertices $x_0$ and $x$.

### 3.2 Loop models

We now proceed to extend the correspondence (3.1) to a pair of correspondences from the set of triangulations $\mathcal{C}_m$ to the respective sets $\mathcal{L}_m^\text{de}$ and $\mathcal{L}_m^\text{di}$ of loop configurations. To this end, let $\tilde{T}_m$ denote the set of planar trees of height $m + 1$ whose vertices, except for the root $x_0$ and vertex $x$, are labelled 0 or 1, that is,

$$\tilde{T}_m := \{(T, \delta) \mid T \in \mathcal{T}_m, \delta : V(T) \rightarrow \{0,1\}\}.$$

For $(T, \delta) \in \tilde{T}_m$, we define the labelling characteristics at height $k + 1$

$$\delta_k := (\delta(v_{k,1}), \ldots, \delta(v_{k,|V_k(T)|}))$$

and set

$$\delta_k := \sum_{v \in V_k(T)} \delta(v)$$

for $k = 1, \ldots, m$. It follows that

$$|\delta| := \sum_{k=1}^{m} \delta_k = \sum_{v \in V(T)} \delta(v)$$

counts the number of 1-labels in $(T, \delta)$. For later convenience, we also introduce

$$\tilde{T}_m(N) := \{(T, \delta) \in \tilde{T}_m \mid T \in \mathcal{T}_m(N)\},$$

$$\tilde{T}_m^\text{ev}(N) := \{(T, \delta) \in \tilde{T}_m \mid T \in \mathcal{T}_m(N), \delta_k \in 2\mathbb{N}_0, k = 1, \ldots, m\},$$
and $\tilde{T}_m^{cv}$ for the similar set without constraints on the number of vertices. Proposition 3.5 below establishes a bijective correspondence between the elements of $L^{de}_m(N)$ and those of $\tilde{T}_m(N)$, while Proposition 3.6 establishes a $2^m$ to 1 correspondence between the elements of $L^{di}_m(N)$ and those of $\tilde{T}_m^{cv}(N)$.

For a triangulated disk $C$, we write $l_k \equiv |S_k|$, $0 \leq k \leq m$, and refer to $l_k$ and $l_{k+1}$ as the boundary lengths of the annulus $A_k$. Any triangulation of $A_k$ can be transformed into one of the form depicted in Figure 7, called a standard triangulation, with the same boundary lengths, $l_k$ and $l_{k+1}$, where $v_k$ denotes the distinguished vertex in $S_k$. This can be achieved by a sequence of local flips of the form

\begin{equation}
\begin{array}{c}
\text{\includegraphics[width=0.1\textwidth]{flip.png}} \\
\end{array}
\end{equation}

as follows. An arbitrary triangulation $T_{A_k}$ of $A_k$ can be described as a sequence of forward- and backward-directed triangles, here denoted by $f$’s and $b$’s, where, by construction, the first entry is a forward-directed triangle. Suppose $T_{A_k}$ is not standard; then there exists at least one $b$ followed by a $f$, i.e. a $bf$ in the sequence. Apply the flip operation (3.3) to the first instance of $bf$, thereby transforming it into an $fb$. Iteratively applying this procedure, one arrives at the standard triangulation of $A_k$.

![Figure 7: Standard triangulation of annulus $A_k$.](image)

The flip operation in (3.3) is readily extended to a flip operation on the similar local components of a loop configuration on $A_k$. In the dense loop model, the extension is given by

\begin{equation}
\begin{array}{c}
\text{\includegraphics[width=0.1\textwidth]{flip_dense.png}} \\
\end{array}
\end{equation}

In the dilute loop model, the extension is given by

\begin{equation}
\begin{array}{c}
\text{\includegraphics[width=0.1\textwidth]{flip_dilute.png}} \\
\end{array}
\end{equation}

We immediately have the following result.

**Lemma 3.1.**

(i) The number of possible dense, respectively dilute, loop configurations on a triangulated annulus $A_k$ only depends on the boundary lengths $l_k$ and $l_{k+1}$, not the details of the triangulation.

(ii) The flip operations (3.4) and (3.5) applied to a dense, respectively dilute, loop configuration, $L$, on a triangulated disk leave $|L|$ and the positions of intersections, hence also $s(L)$, invariant.

A loop configuration on a triangulated annulus $A_k$ is characterised not only by the boundary lengths $l_k$ and $l_{k+1}$, but also by the number and location of the space-like edges which are intersected by loop
segments. Correspondingly, for the cycle $S_k$, $k = 1, \ldots, m$, the intersection characteristics are given by the $l_k$-tuple
\[ n_k = (n_{k,1}, \ldots, n_{k,l_k}) \in \{0, 1\}^{l_k}, \quad k = 1, \ldots, m, \]
where $n_{k,i}$ takes the value $1$ if the $i$'th space-like edge (labelled clockwise from $v_k$) is intersected, and $0$ otherwise. Associated to the intersection characteristics $n_k$, we set
\[ n_k := \sum_{i=1}^{l_k} n_{k,i}, \quad k = 1, \ldots, m. \]

**Remark.** With notation as in Section 2, $s_k(L) = 2n_k$ for $L \in \mathcal{L}_{m+}^d$, while $s_k(L) = n_k$ for $L \in \mathcal{L}_{m-}^d$.

**Lemma 3.2.** Let $C_k$ be a triangulation of the annulus $A_k$ with boundary lengths $l_k$ and $l_{k+1}$, and let $n_k \in \{0, 1\}^{l_k}$ and $n_{k+1} \in \{0, 1\}^{l_{k+1}}$. Then,

(i) $C_k$ admits exactly one dense loop configuration with intersection characteristics $n_k$ and $n_{k+1}$;

(ii) $C_k$ admits exactly two, respectively zero, dilute loop configurations with intersection characteristics $n_k$ and $n_{k+1}$ if the sum $n_k + n_{k+1}$ is even, respectively odd.

**Proof.** By Lemma 3.1, it suffices to consider standard triangulations, which we will do in the following. In the dense loop model, the entries of the intersection characteristics are in one-to-one correspondence with the possible decorations of the associated elementary triangles, as follows:

\[ \begin{array}{c}
\begin{array}{c}
\triangleleft \quad \leftrightarrow \quad n_{k+1,i} = 0, \\
\triangledown \quad \leftrightarrow \quad n_{k+1,i} = 1,
\end{array}
\begin{array}{c}
\triangledown \quad \leftrightarrow \quad n_{k,i} = 0, \\
\bigtriangleup \quad \leftrightarrow \quad n_{k,i} = 1.
\end{array}
\end{array} \]

Since there are no compatibility constraints along time-like edges in the dense loop model, this establishes the claim in this case. In the dilute loop model, the entries $n_{k,i}$ and $n_{k+1,i}$ corresponding to the elementary triangles in Figure 4 are given as follows:

\[ \begin{array}{c}
\begin{array}{c}
\bigtriangleup \quad , \quad \bigtriangleup \quad \rightarrow \quad n_{k+1,i} = 0, \\
\bigtriangleup \quad , \quad \triangleleft \quad \rightarrow \quad n_{k,i} = 0,
\end{array}
\begin{array}{c}
\bigtriangleup \quad , \quad \bigtriangleup \quad \bigtriangledown \quad \rightarrow \quad n_{k+1,i} = 1, \\
\bigtriangleup \quad , \quad \bigtriangledown \quad \rightarrow \quad n_{k,i} = 1.
\end{array}
\end{array} \]

Despite the 2 to 1 nature of these correspondences, there is a unique decorated triangle associated to a given value of $n_{k,i}$ or $n_{k+1,i}$ if the ‘intersectedness’ of the left time-like edge is known. By successive applications of this argument, given the intersectedness of the first time-like edge in the standard triangulation of $A_k$, the decorations of all the forward-directed triangles are determined by the intersection characteristics $n_k$. The intersectedness of the right edge of the last of these triangles is the same as (respectively opposite to) that of the left edge of the first triangle if $n_k$ is even (respectively odd). Repeating the arguments for the backward-directed triangles in $A_k$, we see that, given the intersectedness of the left time-like edge of the first of these triangles (whose space-like edge carries the label $n_{k+1,1}$), all the backward-directed triangles are determined by the intersection characteristics $n_{k+1}$, and the intersectedness of the right edge of the last backward-directed triangle is the same as (respectively opposite to) that of the left edge of the first backward-directed triangle if $n_{k+1}$ is even (respectively odd). Due to the nontrivial compatibility constraints along the time-like edges in the dilute loop model, $n_k + n_{k+1}$ must be even, as observed in (2.3), so the intersectedness of the right edge of the last backward-directed triangle is the same as that of the left edge of the first forward-directed triangle in all cases, in accordance with the periodicity of the annulus. Since the intersectedness of the left time-like edge of the first forward-directed triangle is undetermined by $n_k$ and $n_{k+1}$, this establishes the claim in the dilute loop model case. \qed
Figure 8: The unique dense loop configuration on the standard triangulation of $A_k$ with intersection characteristics $n_k = (1,1,0,0)$ and $n_{k+1} = (0,1,0)$.

To illustrate Lemma 3.2, Figure 8 depicts the unique dense loop configuration on the standard triangulation of $A_k$ with intersection characteristics $n_k = (1,1,0,0)$ and $n_{k+1} = (0,1,0)$, while Figure 9 depicts the two possible dilute loop configurations on the standard triangulation of $A_k$ with intersection characteristics $n_k = (1,1,1,1)$ and $n_{k+1} = (0,1,1)$.

Intersection characteristics of loop configurations on triangulated annuli are readily extended to loop configurations on disk triangulations of height $m$ by specifying $n_k$ for each $k = 1, \ldots, m$. Conversely, we say that the $m$ tuples $n_k \in \{0,1\}^k$, $k = 1, \ldots, m$, form admissible intersection characteristics for a disk triangulation if there exists a corresponding loop configuration. Following Lemma 3.2 and the Remark immediately preceding it, as well as (2.3), such a set of tuples is always admissible in the dense case, and it is admissible in the dilute case if and only if $n_k \in 2\mathbb{N}$, $k = 1, \ldots, m$. Moreover, given a triangulated disk with admissible intersection characteristics, the choice of loop configuration on any one of the triangulated annuli is independent of the choices made for the other triangulated annuli. Thus, by Lemma 3.2 and the proof thereof, we have the following two results.

Figure 9: The two possible dilute loop configurations on the standard triangulation of $A_k$ with intersection characteristics $n_k = (1,1,1,1)$ and $n_{k+1} = (0,1,1)$.

Lemma 3.3. A triangulated disk of height $m$ with admissible intersection characteristics $n_k$, $k = 1, \ldots, m$, admits exactly one dense loop configuration or exactly $2^m$ dilute loop configurations.

Corollary 3.4.

(i) A triangulated cylinder with $N$ vertices admits $2^N$ dense loop configurations or $2^N$ dilute loop configurations.

(ii) A triangulated disk with $N$ vertices admits $2^{N-1}$ dense loop configurations or $2^{N-1}$ dilute loop configurations. Hence,

$$|D_m^d(N)| = |D_m^d(N)|, \quad m, N \in \mathbb{N}.$$  

The parity constraints of the dilute loop configurations compensate for the additional factor of 2 arising from each layer. The next proposition establishes the advertised correspondence between dense loop configurations and labelled trees. The correspondence is illustrated in Figure 10 where tree vertices labelled 1 are indicated with blue circles.

Proposition 3.5. For every $m \in \mathbb{N}_0$ and $N \in \mathbb{N}$, there is a bijective correspondence

$$\tilde{\psi} : D_m^d(N) \to \tilde{T}_m(N)$$

12
Figure 10: Dense loop configuration $L$ and the corresponding labelled planar tree $	ilde{\psi}(L)$. Vertices labelled 1 are indicated with blue circles.

such that if $(T, \delta) = \tilde{\psi}(L)$ then $T = \psi(C)$, where $C$ is the triangulation underlying $L$. Moreover, $|\delta| = s(L)/2$.

Proof. The map $\delta$ in the image $\tilde{\psi}(L) = (T, \delta)$ labels with a 1 any vertex that appears to the left (viewed outwardly) of a space-like edge intersected by two loop arcs, and any other vertex in $V(T)$ with a 0. The vertices $x_0$ and $x$ are not labelled. As $(T, \delta) \in \tilde{T}_m(N)$, this defines the correspondence $\tilde{\psi}$. The bijectivity of $\tilde{\psi}$ is a consequence of the following facts: $\tilde{\psi}$ is bijective; disregarding $x_0$, the vertices of $L \in L_m^{dl}(N)$ and $T = \psi(C)$ coincide; by Lemma 3.3 $L$ is uniquely described by the intersection characteristics $n_k$, $k = 1, \ldots, m$; $(T, \delta)$ is uniquely described by the labelling characteristics $\delta_k$, $k = 1, \ldots, m$; and $\delta_k = n_k$ for $k = 1, \ldots, m$. The relation $|\delta| = s(L)/2$ readily follows.

The following proposition is the dilute counterpart to Proposition 3.5, see Figure 11.

**Proposition 3.6.** For every $m \in \mathbb{N}_0$ and $N \in \mathbb{N}$, there is a $2^m$ to 1 correspondence

$$\hat{\psi} : L_m^{di}(N) \rightarrow \hat{T}_m^{ev}(N)$$

such that if $(T, \delta) = \hat{\psi}(L)$ then $T = \psi(C)$, where $C$ is the triangulation underlying $L$. Moreover, $|\delta| = s(L)$.

Proof. The map $\delta$ in the image $\hat{\psi}(L) = (T, \delta)$ labels with a 1 any vertex that appears to the left (viewed outwardly) of a space-like edge intersected by an arc, and any other vertex in $V(T)$ with a 0. The vertices $x_0$ and $x$ are not labelled. As $(T, \delta) \in \hat{T}_m^{ev}(N)$, this defines the correspondence $\hat{\psi}$. The $2^m$ to 1 property of $\hat{\psi}$ is a consequence of the following facts: $\hat{\psi}$ is bijective; disregarding $x_0$, the vertices of $L \in L_m^{di}(N)$ and $T = \psi(C)$ coincide; by Lemma 3.3 $L$ is one of $2^m$ possible loop configurations admitted by the admissible intersection characteristics $n_k$, $k = 1, \ldots, m$; $(T, \delta)$ is uniquely described by the labelling characteristics $\delta_k$, $k = 1, \ldots, m$; and $\delta_k = n_k$ for $k = 1, \ldots, m$. The relation $|\delta| = s(L)$ readily follows.
Figure 11: Dilute loop configuration $L$ and the corresponding labelled planar tree $\hat{\psi}(L)$. Vertices labelled 1 are indicated with blue circles.

### 3.3 Partition functions

Following Propositions 3.5 and 3.6, we are interested in the tree ensembles $\tilde{T}_m$ and $\tilde{T}^\text{ev}_m$, $m \in \mathbb{N}_0$. The corresponding partition functions are defined as

$$W(g, \alpha) := \sum_{m=0}^{\infty} W_m(g, \alpha), \quad W_m(g, \alpha) := \sum_{(T, \delta) \in \tilde{T}_m} g^{\lvert T \rvert-1} \alpha^{|\delta|}, \quad (3.6)$$

$$W^\text{ev}(g, \alpha) := \sum_{m=0}^{\infty} W^\text{ev}_m(g, \alpha), \quad W^\text{ev}_m(g, \alpha) := \sum_{(T, \delta) \in \tilde{T}^\text{ev}_m} g^{\lvert T \rvert-1} \alpha^{|\delta|}, \quad (3.7)$$

where $\lvert T \rvert$ denotes the number of edges in $T$. The subtraction of 1 from $\lvert T \rvert$ in the exponent of $g$ disregards the contribution from the edge $\{x_0, x\}$, and we note that $W_0(g, \alpha) = W_0^\text{ev}(g, \alpha) = 1$. It follows from Proposition 3.5 that

$$Z^\text{de}_m(g, \alpha) = W_m(g, \alpha^2),$$

and consequently

$$Z^\text{de}(g, \alpha) = W(g, \alpha^2). \quad (3.8)$$

It likewise follows from Proposition 3.6 that

$$Z^\text{di}_m(g, \alpha) = 2^m W^\text{ev}_m(g, \alpha),$$

and consequently

$$Z^\text{di}(g, \alpha) = \sum_{m=0}^{\infty} Z^\text{di}_m(g, \alpha) = \sum_{m=0}^{\infty} 2^m W^\text{ev}_m(g, \alpha).$$

4 Tree partition function analysis

We now turn to an analysis of the tree partition functions $W(g, \alpha)$ and $W^{ev}(g, \alpha)$, with a view to determine the critical behaviour of the dense and dilute loop models. Regarding the dilute case, we consider the height-coupled partition function

$$W^{ev}(g, \alpha, k) := \sum_{m=0}^{\infty} k^m W_m^{ev}(g, \alpha),$$

where $k > 0$ is an arbitrary height coupling, such that $Z^{di}(g, \alpha)$ is recovered for $k = 2$:

$$Z^{di}(g, \alpha) = W^{ev}(g, \alpha, 2).$$

In Section 4.1 we analyse the partition functions $W(g, \alpha)$, $W^{ev}(g, \alpha)$ and $W^{ev}(g, \alpha, k)$ for $\alpha = 0$ corresponding to unlabelled planar trees, while in Section 4.2 we consider the case where $\alpha \in (0, 1]$.

4.1 Planar trees

Let $T$ denote the set of planar trees with root of degree 1 (hence of height at least 1), that is,

$$T := \bigcup_{m=0}^{\infty} T_m.$$

The partition function, $W(g)$, for trees in $T$, again disregarding the contribution from the single edge emanating from the root, is defined by

$$W(g) := \sum_{T \in T} g^{|T|} = \sum_{m=0}^{\infty} W_m(g), \quad W_m(g) := \sum_{T \in T_m} g^{|T|},$$

where $W_m(g)$ is the similar partition function restricted to trees of height $m + 1$. It readily follows that

$$W(g, 0) = W^{ev}(g, 0) = W^{ev}(g, 0, 1) = W(g).$$

As $W(g)$ is the generating function of rooted planar trees up to a factor of $\frac{1}{g}$, it follows (see e.g. [37]) that

$$W(g) = \frac{1}{1 - g W(g)},$$

from which one obtains

$$W(g) = \frac{1 - \sqrt{1 - 4g}}{2g},$$

which is analytic on the disk

$$\mathbb{D} = \{ g \in \mathbb{C} | |g| < \frac{1}{4} \},$$

with a square-root singularity at $g_c = \frac{1}{4}$. We note that $W(0) = 1$ and $W(\frac{1}{4}) = 2$.

Specialising the labelling parameter in (4.1) to $\alpha = 0$, the expression reduces to a height-coupled partition function generalising the tree partition function $W(g)$:

$$W^{ev}(g, 0, k) = \sum_{m=0}^{\infty} k^m W_m(g), \quad k > 0.$$

For $m \in \mathbb{N}_0$, let $X_m(g)$ be the partition function of trees in $T$ with height at most $m + 1$. It follows that

$$W_m(g) = X_m(g) - X_{m-1}(g),$$
where $X_{-1}(g) \equiv 0$, and that

$$X_m(g) = \frac{1}{1 - gX_{m-1}(g)}, \quad m \geq 0. \quad (4.5)$$

This recursion relation is solved by

$$X_m(g) = \frac{U_m\left(\frac{1}{2\sqrt{g}}\right)}{\sqrt{g}U_{m+1}\left(\frac{1}{2\sqrt{g}}\right)},$$

where $U_n(x)$ is the $n$'th Chebyshev polynomial of the second kind (with $U_{-1}(x) \equiv 0$). It follows that

$$W_m(g) = \frac{1}{\sqrt{g}U_m\left(\frac{1}{2\sqrt{g}}\right)} U_m\left(\frac{1}{2\sqrt{g}}\right),$$

and since

$$U_n(x) = 2^n \prod_{j=1}^{n} \left(x - \cos \frac{j\pi}{n+1}\right), \quad n \in \mathbb{N}_0,$$

$X_m(g)$ is analytic on the disk

$$\mathbb{D}_m = \{g \in \mathbb{C} \mid |g| < g_m\}, \quad g_m = \frac{1}{4}\left(1 + \tan^2 \frac{\pi}{m+2}\right),$$

with a simple pole at $g_m$ (noting that $g_0 = \infty$).

Because the coefficients defining $X_m(g)$ as a power series in $g$ are nonnegative, it follows that $X_m(g)$ is divergent for $g > g_m$. Since $g_m \to \frac{1}{4}$ as $m \to \infty$, this implies that $W(g,0,k)$ is divergent for $g > \frac{1}{4}$, so the radius of convergence $g_c(k)$ of $W(g,0,k)$ for fixed $k$ is at most $\frac{1}{4}$ for any $k > 0$. The following lemma is a step towards the determination of $g_c(k)$ for all $k > 0$, completed in Proposition 4.3 below.

**Lemma 4.1.** For $g \in (0, \frac{1}{4})$ and $m \in \mathbb{N}$, we have

$$\frac{\phi^2(W(g) - 1)}{W(g)}(W(g) - 1)^m < W_m(g) < (W(g) - 1)^m,$$

where $\phi$ is Euler’s function.

**Proof.** From the recursion relation (4.5), we get

$$W_m = X_m - X_{m-1} = \frac{g(X_{m-1} - X_{m-2})}{(1 - gX_{m-1})(1 - gX_{m-2})} = g(X_{m-1} - X_{m-2})X_mX_{m-1},$$

and iteratively applying this, we obtain (for $m \geq 1$)

$$W_m = g^mW^{2m-2}X_m \prod_{i=1}^{m-1} \left(\frac{X_i}{W}\right)^2. \quad (4.6)$$

Since $X_i$ is increasing and converges to $W$ as $i \to \infty$, it follows that $1 < X_i < W$ for $i \geq 1$, so $\frac{X_i}{W} < 1$, allowing us to use (4.3) to conclude that

$$W_m < (W - 1)^m.$$ 

This establishes the upper bound.

For the lower bound, we have

$$W - X_m = g(W - X_{m-1})WX_m = (W - 1)g^mW^{2m} \prod_{i=1}^{m} \frac{X_i}{W} < (W - 1)^m,$$
where we have used (4.3) and that \(1 < W < 2\). It follows that
\[
\frac{X_i}{W} = 1 - \frac{W - X_i}{W} > 1 - \frac{(W - 1)i}{W} > 1 - (W - 1)i.
\]
Since \(0 < W - 1 < 1\), we have
\[
\prod_{i=1}^{m} (1 - (W - 1)i) > \prod_{i=1}^{\infty} (1 - (W - 1)i) = \phi(W - 1).
\]
Returning to (4.6), we thus find that
\[
W_m = g_m W^{2m} \prod_{i=1}^{m} \left( \frac{X_i}{W} \right)^2 > \frac{\phi^2(W - 1)}{W} (W - 1)^m,
\]
thereby establishing the lower bound and completing the proof.

The following corollary immediately follows.

**Corollary 4.2.** For \(k > 0\) and \(g \in (0, \frac{1}{4})\), we have
\[
\frac{\phi^2(W(g) - 1)}{W(g)} \sum_{m=0}^{\infty} (k(W(g) - 1))^m \leq W(g, 0, k) \leq \sum_{m=0}^{\infty} (k(W(g) - 1))^m.
\]

**Proposition 4.3.** The critical coupling for \(W(g, 0, k)\) is given by
\[
g_c(k) = \begin{cases} \frac{1}{4}, & k \in (0, 1], \\ \frac{k}{(k+1)^2}, & k \in (1, \infty). \end{cases}
\]

**Proof.** As mentioned previously, we have \(g_c(k) \leq \frac{1}{4}\). For \(k \leq 1\), we clearly have \(W(g, k) \leq W(g)\), so \(g_c(k) = \frac{1}{4}\). For \(k > 1\), Corollary 4.2 implies that \(W(g, 0, k)\) is finite if and only if \(k(W(g) - 1) < 1\).

It follows that \(g_c(k) = \frac{k}{(k+1)^2}\).

For \(k < 1\), it can be shown that all \(g\)-derivatives of \(W(g, 0, k)\) from the left at \(g = \frac{1}{4}\) are finite, but this fact is not essential for the discussion in Section 5. For \(k = 1\), we have \(W(g, 0, 1) = W(g)\), whose singular nature was recalled above. For \(k > 1\), it follows from Corollary 4.2 and the analyticity of \(W(g)\) at \(g_c(k) < \frac{1}{4}\) that \(W(g, 0, k)\) has a simple pole at \(g_c(k)\). We refrain from giving the detailed arguments here (see [36]) but will assume their validity in the following.

### 4.2 Labelled planar trees

We now consider the presence of a labelling with the associated coupling \(\alpha \in (0, 1]\). Summing over the labels \(\delta\) in the expression (3.6) for \(W_m(g, \alpha)\) yields
\[
W_m(g, \alpha) = \sum_{T \in \mathcal{T}_m} (g(1 + \alpha))^{|T|-1} = W_m(g(1 + \alpha)), \tag{4.7}
\]
where we have used (4.2). It follows that
\[
W(g, \alpha) = W(g(1 + \alpha)), \tag{4.8}
\]

17
whose critical $g$-coupling is given by $g = \frac{1}{4(1 + \alpha)}$.

Likewise, summing over the admissible labels in the expression (3.7) for $W_m^\text{ev}(g, \alpha)$ yields

$$W_m^\text{ev}(g, \alpha) = \sum_{T \in T_m} g^{|T| - 1} \prod_{i=1}^{m} \frac{1}{2} [(1 + \alpha)^{n_i} + (1 - \alpha)^{n_i}],$$

(4.9)

where $n_i = |V_i(T)|$ is the number of vertices in $T$ at height $i + 1$. Note that $W^\text{ev}(g, \alpha)$ naturally extends to an even function of $\alpha \in [-1,1]$. Contrary to the case $W_m(g, \alpha)$ in (4.7), we do not have a closed-form expression for $W_m^\text{ev}(g, \alpha)$. Instead, we may gain insight into the critical behaviour of $W_m^\text{ev}(g, \alpha)$ by bounding the function by (partition) functions whose critical behaviour is understood. For $\alpha \in (0,1]$, we thus use

$$(1 + \alpha)^{n} \leq (1 + \alpha)^{n} + (1 - \alpha)^{n} \leq 2(1 + \alpha)^{n - 1}, \quad n \in \mathbb{N},$$

and

$$\sum_{i=1}^{m} n_i = |T| - 1, \quad T \in T_m,$$

to obtain

$$W^\text{ev}\left(g(1 + \alpha), 0, \frac{k}{2}\right) \leq W^\text{ev}(g, \alpha, k) \leq W^\text{ev}\left(g(1 + \alpha), 0, \frac{k}{1+\alpha}\right).$$

(4.10)

We will use this in our analysis of $Z_{\text{de}}(g, \alpha)$ in Section 5.5.

## 5 Critical behaviour of loop models

In this section, we use results from Sections 3 and 4 together with a transfer matrix formalism to examine the critical behaviour of the dense and dilute loop models. This approach is first applied to the pure CDT model and readily extended to the dense loop model by shifting the coupling constant. It is subsequently used to gain insight into the dilute loop model. Focus here is on the critical behaviour of the models; algebraic aspects of the transfer matrix formalism will be discussed elsewhere.

### 5.1 Dense loop model

It follows from (3.8), (4.8) and (4.8) that

$$Z_{\text{de}}(g, \alpha) = W(g(1 + \alpha^2)) = \frac{1 - \sqrt{1 - 4g(1 + \alpha^2)}}{2g(1 + \alpha^2)}. \quad (5.1)$$

This expression implies that the critical coupling for the dense loop model, $g_{\text{de}}(\alpha)$, and the corresponding value of the partition function, $Z_{\text{de}}^c(\alpha) := Z_{\text{de}}(g_{\text{de}}(\alpha), \alpha)$, are given by

$$g_{\text{de}}(\alpha) = \frac{1}{4(1 + \alpha^2)}, \quad Z_{\text{de}}^c(\alpha) = 2.$$

**Remark.** The correspondence between causal triangulations on the sphere and rooted trees can be viewed as a particular instance of Schaeffer’s bijection [38], where each pair of triangles sharing a space-like edge form a quadrangle [14]. In the dense loop model, such a quadrangle can then be decorated in two ways: (i) with two vertical arcs (both intersecting the shared space-like edge) or (ii) with two horizontal arcs (not intersecting the space-like edge). We emphasise that there are no compatibility constraints between the decorated quadrangles. The expression (5.1) now follows by assigning the weight $ga^2$ to the quadrangle in case (i) and $g$ in case (ii).
It also follows that the behaviour of $Z\text{de}(g, \alpha)$ near the critical point is the same as for pure CDT:

$$Z\text{de}(g, \alpha) \sim Z_c\text{de}(\alpha) - c_\alpha \sqrt{g\text{de}(\alpha) - g},$$  \hspace{1cm} (5.2)

where $c_\alpha = 4\sqrt{1 + \alpha^2}$ is $g$-independent.

By differentiating the expression (4.2) for $W(g)$, one can express the average value of $|T|$ for $T \in T$ as

$$\frac{1}{W(g)} \sum_{T \in T} |T| g^{\text{deg}(T)} = 1 + \frac{gW'(g)}{W(g)} = \frac{2g}{\sqrt{1 - 4g(1 - \sqrt{1 - 4g})}},$$

which is seen to have a square-root divergence at $g_c = \frac{1}{4}$. This reflects the fact that, close to the critical point, the large triangulations yield the dominant contribution to $W(g)$. A precise definition of the limiting distribution of large triangulations in the form of a measure on causal triangulations of infinite size (or radius) is given in [14]. For such infinite triangulations $C$ with central vertex $x$, the ball of radius $R$ around $x$ is defined as

$$B(x, R) := \{v \in V(C) | d_C(x, v) \leq R\},$$

where $d_C$ denotes the graph distance on $C$. The Hausdorff dimension $d_H$ of $C$ is then defined as the polynomial growth rate of the number of vertices, $|B(x, R)|$, as a function of $R$, that is,

$$d_H(C) := \lim_{R \to \infty} \frac{\ln |B(x, R)|}{\ln R},$$  \hspace{1cm} (5.3)

provided the limit exists. For pure CDT, it is shown in [14] that $d_H = 2$ almost surely.

As a consequence of (5.1) and (5.2), the same arguments apply to the present case, characterised by $Z\text{de}(g, \alpha)$ with critical coupling $g_c\text{de}(\alpha)$, and yield the same value for the Hausdorff dimension:

$$d_H = 2 \text{ (almost surely)}.\,$$

Hence, the coupling of the dense loop model to CDT does not influence the statistical behaviour of the underlying triangulations. This is analogous to what is seen for the Ising model coupled to a random planar tree, where a relation similar to (5.2) can be derived [39].

5.2 Pure CDT transfer matrix

To analyse the critical behaviour of the dilute loop model in Section 5.5, we will combine results on the corresponding labelled tree model obtained in Sections 3 and 4 with insight gained by applying a transfer matrix formalism. It is convenient to develop first the similar approach in the pure CDT model, where transfer matrices have been previously discussed in [35, 40, 20] and implicitly already in [11]. Our focus and methods for investigating the transfer matrix eigenvalues are, however, different and do not depend on the explicit evaluation of the eigenvalues.

The transfer matrix formalism views the triangulated disk as a concatenation of triangulated annuli. A compatibility condition is then enforced along the shared boundaries where two annuli are concatenated. In the pure CDT case, the only constraint is that the boundary lengths agree, that is, the matching boundaries must contain the same number of space-like edges. As the boundary length can take on any positive integer value, it is natural to let the Hilbert space of square summable complex sequences,

$$l_2(\mathbb{N}) := \{(x_n)_{n \in \mathbb{N}} | \sum_{n=1}^{\infty} |x_n|^2 < \infty; x_i \in \mathbb{C}, i \in \mathbb{N}\},$$

encode the degrees of freedom along the space-like boundaries. Here, $n$ labels the length of a space-like boundary component of a triangulated annulus. We shall view the transfer matrix $T$, whose matrix
elements $T_{r,s}$ with respect to the standard orthonormal basis of $l_2(\mathbb{N})$ are given in (5.4), as an operator on $l_2(\mathbb{N})$. In the following, we use Dirac notation where $|w\rangle$ is a sequence in $l_2(\mathbb{N})$ with coordinates $w_n$, $n \in \mathbb{N}$.

To take into account the distinguished vertex on each cycle, we only consider annulus triangulations where the first triangle (relative to the distinguished vertex) is forward-directed. With $s$ and $r$ denoting the number of lower, respectively upper, space-like edges of the annulus, we set

$$T_{r,s}(g) := \left( \frac{r + s - 1}{r} \right) g^{\frac{r+s}{2}}, \quad (5.4)$$

where the combinatorial factor counts the number of ways the $r$ backward-directed and $(s - 1)$ forward-directed triangles can be concatenated to the right (viewed outwardly) of the distinguished forward-directed triangle. As in [11, 35], the weight $g^{\frac{r}{2}}$ encodes that a weight $g^{\frac{1}{2}}$ has been attributed to each space-like edge of the annulus, ensuring that a shared space-like edge between a pair of concatenated annuli is assigned the familiar weight $g$.

Although $T_{r,s}(g)$ is not symmetric in $r$ and $s$, the operator $T(g)$ is symmetrisable, admitting a factorisation in terms of a diagonal operator $D$ and a symmetric operator $K(g)$,

$$T(g) = DK(g),$$

whose matrix elements are given by

$$D_{r,s} := \frac{\delta_{r,s}}{r}, \quad K_{r,s}(g) := \frac{(r+s-1)!}{(r-1)!(s-1)!} g^{\frac{r+s}{2}}.$$

**Proposition 5.1.** The operator $K(g)$ is trace-class for $g \in \mathbb{D}$, it is positive definite for $g \in (0, \frac{1}{4})$, and the function $h \mapsto K(h^2)$ is analytic on $\{ h \in \mathbb{C} \mid |h| < \frac{1}{2} \}$.

**Proof.** Note first that, for fixed $s$, the sequence $(K_{r,s}(g))_{r \in \mathbb{N}}$ is square summable provided $|g| < 1$. Hence, the operator $K(g)$ is well defined for $|g| < 1$ on the dense subspace $V$ of sequences with only finitely many non-vanishing entries. For $n \in \mathbb{N}$, let $P_n$ be the orthogonal projection in $l_2(\mathbb{N})$ onto the subspace spanned by vectors $|w\rangle$ whose entries $w_r$ vanish for $r > n$. Then, the operator $K_n(g) := P_n K(g) P_n$ is of finite rank and hence is bounded on $l_2(\mathbb{N})$, with matrix elements

$$K_n(g)_{r,s} = \begin{cases} K_{r,s}(g), & r, s \leq n, \\ 0, & \text{otherwise.} \end{cases}$$

Moreover, $K_n(g)$ is positive semidefinite for $g \in [0,1)$ since the identity

$$\frac{(r+s-1)!}{(r-1)!(s-1)!} = \sum_{k \geq 1} k \binom{s}{k} \binom{r}{k}$$

implies

$$|w\rangle K_n(g) |w\rangle = \sum_{k=1}^{n-1} \left| \sum_{s=k}^{n} \binom{s}{k} w_s g^{\frac{s}{2}} \right|^2 \geq 0.$$ \hspace{1cm} (5.5)

Its trace norm is given by

$$\|K_n(g)\|_1 = \text{tr} K_n(g) = \sum_{s=1}^{n} \sum_{k=1}^{s} \binom{s}{k} (s-1) g^{s} \leq \sum_{s=1}^{\infty} s \binom{2s-1}{s} g^{s} = \frac{g}{(1 - 4g)^{\frac{1}{2}}},$$ \hspace{1cm} (5.6)

where the last equality is valid for $g \in (0, \frac{1}{4})$. It follows, in particular, that the operator norms $\|K_n(g)\|$ are uniformly bounded in $n$ for any fixed $g \in [0, \frac{1}{4})$. Since $\langle v | K_n(g) | w \rangle \rightarrow \langle v | K(g) | w \rangle$ as $n \rightarrow \infty$ for
all \( v, w \in V \), it follows that \( K(g) \) extends to a bounded operator on \( l_2(\mathbb{N}) \) that equals the weak limit of \( (K_n(g))_{n \in \mathbb{N}} \) for \( g \) in this interval. Due to (5.6), it now follows from Theorem 10 in Section 2.4 of [42] that \( K(g) \) is trace-class with trace norm given by

\[
\|K(g)\|_1 = \text{tr} K(g) = \frac{g}{(1 - 4g)^2}.
\]

Letting \( n \to \infty \) in (5.5), it follows that 

\[
\sum_{s=k}^{\infty} \binom{s}{k} w_s g^{\frac{s}{2}} = 0
\]

for all \( k \geq 1 \). Evidently, this sum is convergent for \( |g| < 1 \) and

\[
\sum_{s=k}^{\infty} \binom{s}{k} w_s g^{\frac{s}{2}} = \frac{g^{\frac{1}{2}}}{k!} f^{(k)}(g^{\frac{1}{2}}),
\]

where \( f^{(k)}(g^{\frac{1}{2}}) \) is the \( k \)'th derivative of the analytic function

\[
f(z) = \sum_{s=1}^{\infty} w_s z^s, \quad |z| < 1,
\]

evaluated at \( z = g^{\frac{1}{2}} \). It follows that, for \( g \neq 0 \), \( \langle w|K(g)|w \rangle \) vanishes if and only if \( f(z) = 0 \), that is, \( w_s = 0 \) for all \( s \). This shows that \( K(g) \) is positive definite.

Let now \( g \in \mathbb{D} \) be arbitrary and write \( g = |g| e^{i\theta} \). Then,

\[
K(g) = U(\theta)K(|g|)U(\theta),
\]

where \( U(\theta) \) is the diagonal unitary operator with matrix elements

\[
U_{r,s}(\theta) = e^{\frac{ir\theta}{2}} \delta_{r,s}.
\]

It follows that \( K(g) \) is well-defined and trace-class for all \( g \in \mathbb{D} \), with

\[
\|K(g)\|_1 = \text{tr} |K(g)| = \|K(|g|)\|_1.
\]

It is evident that \( g \to \langle v|K(g)|w \rangle \) is analytic on \( \mathbb{D} \) for all \( v, w \in V \), so \( K(g) \) is analytic on \( \mathbb{D} \) as a function of \( \sqrt{g} \), in the sense of Kato (see [41] Section XII.2).

Since \( D \) is a bounded operator, it follows that the transfer operator \( T(g) \) is trace-class for \( g \in (0, \frac{1}{4}) \) with

\[
\text{tr}(T(g)) = \sum_{s=1}^{\infty} T_{s,s}(g) = \frac{1 - \sqrt{1 - 4g}}{2 \sqrt{1 - 4g}}.
\]

Since the matrix elements of \( K(g) \) are positive for \( g \in (0, \frac{1}{4}) \), it is a consequence of the Perron-Frobenius theorem (see e.g. Theorem XIII.43 in [41]) that \( K(g) \) has a non-degenerate positive largest eigenvalue, which equals the operator norm \( \|K(g)\|_1 \), and the corresponding normalised eigenvector has positive entries only. By the Kato-Rellich theorem, see Theorem XII.8 in [41], this eigenvalue is an analytic function of \( g \) on \( (0, \frac{1}{4}) \), and one can multiply the corresponding normalised eigenvector by a phase such that the entries of the product are analytic functions of \( g \) on \( (0, \frac{1}{4}) \). Since \( D \) is diagonal and positive definite, these statements also hold for \( D^{1/2}K(g)D^{1/2} \).
For \( m \neq 0 \), the fixed-height pure CDT partition function is given by \( Z_m(g) = W_m(g) \) and is expressible as a matrix element:

\[
Z_m(g) = \langle v(g) | T^{m-1}(g) | v(g) \rangle, \quad m \in \mathbb{N},
\]

where \( T^{m-1}_{r,s}(g) \equiv (T^{m-1}(g))_{r,s} \) and where \( v(g) \in l_2(\mathbb{N}) \) has entries

\[
v_n(g) := g^n, \quad n \in \mathbb{N}.
\]

This expression for \( Z_m(g) \) corresponds to a sum over all possible causal sphere triangulations of height \( m \), as depicted on the left in Figure 12.

We now define the time-periodic partition functions by

\[
Z^\text{per}_m(g) := \text{tr}(T^{m-1}(g)), \quad m \geq 2.
\]

Note that \( Z^\text{per}_m(g) \) can be expressed as a sum over triangulations of a cylinder of height \((m - 1)\) whose boundary cycles, \( S_1 \) and \( S_m \), have equal (but arbitrary) length, and with a weight \( g^{\frac{m}{2}} \) associated to each elementary triangle. Alternatively, the weights can be assigned to the space-like edges; however, this requires the space-like edges within the bulk be assigned the weight \( g \) and those on the boundary cycles the weight \( g^{\frac{m}{2}} \).

Since the trace of a positive trace-class operator \( O \) equals the sum of its eigenvalues [42], it follows that \( \text{tr}(O^n) \leq (\text{tr} O)^n, \quad n \in \mathbb{N} \), and hence that

\[
Z^\text{per}_m(g) \leq (\text{tr} T(g))^{m-1}.
\]

**Lemma 5.2.** For each \( m \geq 1 \) and \( g \in [0, \frac{1}{4}) \),

\[
Z_m(g) \leq Z^\text{per}_{m+1}(g).
\]

**Proof.** Let \( \bar{C} \) be a causal sphere triangulation of height \( m \), with notation as in Section 2.1. Then, (i) remove the \( |S_1| \) backward-directed triangles with space-like edges in \( S_1 \), and (ii) place them to the right (viewed upwardly) of the \( |S_m| \) forward-directed triangles with space-like edges in \( S_m \), thereby creating an annulus \( A_m \) between \( S_m \) and the new outer boundary \( S_{m+1} \). This is illustrated in Figure 12 and yields a...
triangulation, $\bar{C}'$, of a cylinder of height $m$, of the form contributing to $Z_{m+1}^{per}(g)$. In fact, as a consequence of the conservation of triangulation area under $\bar{C} \to \bar{C}'$, the contribution of $\bar{C}'$ to $Z_{m+1}^{per}(g)$ is the same as the contribution of $\bar{C}$ to $Z_m(g)$. Finally, the map $\bar{C} \to \bar{C}'$ is evidently injective but not surjective, since the top annulus of $\bar{C}'$ is restricted to be of standard form. This establishes the inequality (5.5). \hfill \Box

It follows from the cyclicity of the trace in (5.8) that

$$Z_m^{per}(g) = \text{tr}((D^{\frac{1}{2}} K(g) D^{\frac{1}{2}})^{m-1}), \quad m \geq 2.$$ 

The following proposition describes the behaviour of the largest eigenvalue as $g$ approaches the critical point. Although it does not provide any additional information for understanding the partition function of pure CDT, the method is general and will be used for the analysis of the dilute loop model in Section 5.5.

**Proposition 5.3.** The largest eigenvalue $\lambda_1(g)$ of $D^{\frac{1}{2}} K(g) D^{\frac{1}{2}}$ satisfies

$$\lambda_1(g) \not\sim 1 \quad \text{as} \quad g \not\sim \frac{1}{4}.$$ 

**Proof.** All matrix elements of $D^{\frac{1}{2}} K(g) D^{\frac{1}{2}}$ are strictly increasing positive functions of $g$. By the variational principle (see Theorem XIII.1 in [11]), it follows that $\lambda_1(g)$ is strictly increasing for $g \in (0, \frac{1}{4})$. We also note that $\lim_{g \to 0} \lambda_1(g) = 0$. If unlikely to cause confusion, arguments of functions may be omitted in the following.

If $\lambda_1 \leq c_1$ for some constant $c_1 < 1$, then $(1 - k D^{\frac{1}{2}} K D^{\frac{1}{2}})^{-1}$ is a bounded operator for $k \in [1, c_1^{-1})$ and

$$\sum_{m=1}^{\infty} k^m Z_m^{per} = \sum_{m=1}^{\infty} \text{tr}((k D^{\frac{1}{2}} K D^{\frac{1}{2}})^m) = k \text{tr} \left(D^{\frac{1}{2}} K D^{\frac{1}{2}}(1 - k D^{\frac{1}{2}} K D^{\frac{1}{2}})^{-1}\right) \leq k \| (1 - k D^{\frac{1}{2}} K D^{\frac{1}{2}})^{-1} \| \text{tr}(T) < \infty$$

for all $g \in (0, \frac{1}{4})$. By (5.9), this implies

$$W(g, 0, k) = 1 + \sum_{m=1}^{\infty} k^m Z_m(g) < \infty,$$

in contradiction to Proposition 4.3, which says that the critical coupling for $W(g, 0, k)$ satisfies $c_c(k) < \frac{1}{4}$ for $k > 1$. This shows that $\lim_{g \to \frac{1}{4}} \lambda_1(g) = 1$.

Now, suppose this limit is strictly greater than 1. Then, there would exist $g_0 < \frac{1}{4}$ such that $\lambda_1(g_0) = 1$. Let $|w^{(1)}(g)\rangle$ denote the normalised (analytic) eigenvector of $D^{\frac{1}{2}} K D^{\frac{1}{2}}$ with positive coordinates for $g$ in an interval $I$ around $g_0$. For $I$ sufficiently small, there exists a constant $c > 0$ such that

$$\langle v | D^{\frac{1}{2}} | w^{(1)} \rangle \langle w^{(1)} | D^{-\frac{1}{2}} | v \rangle \geq c$$

for $g \in I$. As above, we suppress the $g$ dependence and denote $|v(g)\rangle$ and $|w^{(1)}(g)\rangle$ by $|v\rangle$ and $|w^{(1)}\rangle$, respectively. Let $\lambda_2 \geq \lambda_3 \geq \ldots$ denote the remaining eigenvalues (multiplicities included) of $D^{\frac{1}{2}} K D^{\frac{1}{2}}$ and $\{|w^{(n)}\rangle | n \in \mathbb{N}\}$ a corresponding orthonormal set of eigenvectors. For $g < g_0$, the partition function
satisfies
\[ Z(g) - 1 = \sum_{n=1}^{\infty} \langle v | D^{\frac{1}{2}} (D^{\frac{1}{2}} K D^{\frac{1}{2}})^{m-1} D^{-\frac{1}{2}} | v \rangle \]
\[ = \sum_{n,m=1}^{\infty} \langle v | D^{\frac{1}{2}} (D^{\frac{1}{2}} K D^{\frac{1}{2}})^{m-1} | w^{(n)} \rangle \langle w^{(n)} | D^{-\frac{1}{2}} | v \rangle \]
\[ = \langle v | D^{\frac{1}{2}} | w^{(1)} \rangle \langle w^{(1)} | D^{-\frac{1}{2}} | v \rangle \sum_{m=1}^{\infty} \lambda_1^{m-1} + \sum_{m=1}^{\infty} \sum_{n=2}^{\infty} \lambda_n^{m-1} \langle v | D^{\frac{1}{2}} | w^{(n)} \rangle \langle w^{(n)} | D^{-\frac{1}{2}} | v \rangle \]
\[ \geq \frac{c}{1 - \lambda_1} + \sum_{n=2}^{\infty} \frac{\langle v | D^{\frac{1}{2}} | w^{(n)} \rangle \langle w^{(n)} | D^{-\frac{1}{2}} | v \rangle}{1 - \lambda_n}, \]
and it follows that
\[ Z(g) \geq 1 + \frac{c}{1 - \lambda_1} - \sum_{n=2}^{\infty} \frac{\langle v | D^{\frac{1}{2}} | w^{(n)} \rangle \langle w^{(n)} | D^{-\frac{1}{2}} | v \rangle}{1 - \lambda_n} \geq 1 + \frac{c}{1 - \lambda_1} - \frac{\| D^{\frac{1}{2}} v \| \| D^{-\frac{1}{2}} v \|}{1 - \lambda_2}. \quad (5.10) \]

Note that, although \( D^{-\frac{1}{2}} \) is unbounded, \( D^{-\frac{1}{2}} v \) belongs to \( l_2(\mathbb{N}) \), as the entries of \( v(g) \) decay exponentially. It follows from (5.10) that \( Z(g) \) diverges as \( g \) approaches \( g_0 \) from below, in contradiction to the fact that \( Z(g) \) is analytic on \( \mathbb{D} \). It follows that \( \lim_{g \to g_0} \lambda_1(g) = 1 \), and since \( \lambda_1(g) \) is strictly increasing for \( g \in (0, \frac{1}{4}) \), this concludes the proof.

This completes our transfer matrix analysis of the pure CDT model.

### 5.4 Dense loop model revisited

Generalising (5.1), the fixed-height dense loop model partition function is expressible in terms of the similar pure CDT partition function as
\[ Z^{de}_m(g, \alpha) = Z_m(g(1 + \alpha^2)). \]

Analogues of the pure CDT transfer matrix \( T(g) \) and the related operator \( K(g) \) similarly satisfy \( T^{de}(g, \alpha) = T(g(1 + \alpha^2)) \) and \( D^{\frac{1}{2}} K^{de}(g, \alpha) D^{\frac{1}{2}} = D^{\frac{1}{2}} K(g(1 + \alpha^2)) D^{\frac{1}{2}} \). Both \( T^{de}(g, \alpha) \) and \( K^{de}(g, \alpha) \) are positive definite and trace-class for \( g \in (0, \frac{1}{4(1+\alpha^2)}) \), with
\[ \text{tr}(T^{de}(g, \alpha)) = \frac{1 - \sqrt{1 - 4g(1 + \alpha^2)}}{2 \sqrt{1 - 4g(1 + \alpha^2)}}, \quad \text{tr}(K^{de}(g, \alpha)) = \frac{g(1 + \alpha^2)}{\left(1 - 4g(1 + \alpha^2)\right)^{\frac{3}{2}}}. \]

Moreover, as counterpart to Proposition 5.3 we have that, for \( \alpha \in [0, 1] \), the largest eigenvalue \( \lambda_1(g, \alpha) \) of \( D^{\frac{1}{2}} K^{de}(g, \alpha) D^{\frac{1}{2}} \) approaches 1 from below as \( g \) approaches \( g^{de}_c(\alpha) = \frac{1}{4(1+\alpha^2)} \) from below.

### 5.5 Dilute loop model

Recalling (3.9) and (4.9), the transfer matrix for the dilute loop model has entries given by
\[ T^{di}_{r,s}(g, \alpha) = \begin{pmatrix} r & s - 1 \\ r & s \end{pmatrix} \left[ (1 + \alpha)^r + (1 - \alpha)^s \right] \frac{1}{2} \left[ (1 + \alpha)^r + (1 - \alpha)^s \right] \frac{1}{2} g^{\frac{r+s}{2}}, \]
normalised such that, in analogy with (5.7),
\[ Z^{di}_m(g, \alpha) = \langle v(g, \alpha) | (T^{di}(g, \alpha))^{m-1} | v(g, \alpha) \rangle, \quad m \in \mathbb{N}, \]
\[ Z^{di}_0(g, \alpha) = \langle v(g, \alpha) | v(g, \alpha) \rangle. \]
where the coordinates of the vector \( v(g, \alpha) \in l^2(\mathbb{N}) \) are defined by

\[
v_n(g, \alpha) := [(1 + \alpha)^n + (1 - \alpha)^n]^{\frac{1}{2}} g^{\frac{n}{2}}, \quad n \in \mathbb{N}.
\]

Recalling that \( Z_0^{di}(g, \alpha) = 1 \), the full partition function is thus given by

\[
Z^{di}(g, \alpha) = 1 + \sum_{m=1}^{\infty} \langle v(g, \alpha) | (T^{di}(g, \alpha))^{m-1} | v(g, \alpha) \rangle.
\]

The transfer matrix \( T^{di}(g, \alpha) \) is not symmetric but can be symmetrised by the same diagonal operator as \( T(g) \), that is,

\[
T^{di}(g, \alpha) = 2DK^{di}(g, \alpha),
\]

where

\[
K^{di}_{r,s}(g, \alpha) = \frac{1}{2} \frac{(r + s - 1)!}{(r - 1)!(s - 1)!} \frac{1}{g} ((1 + \alpha)^r + (1 - \alpha)^r)^{\frac{1}{2}} [((1 + \alpha)^s + (1 - \alpha)^s)^{\frac{1}{2}}].
\]

We also note that

\[
K^{di}(g, 0) = K(g).
\]

Essentially repeating the arguments in the analysis of the pure CDT model in Section 5.3, we see that \( K^{di}(g, \alpha) \) and \( D^{\frac{1}{2}} K^{di}(g, \alpha) D^{\frac{1}{2}} \) are positive definite trace-class operators on \( l^2(\mathbb{N}) \) for \( g \in (0, \frac{1}{4(1+\alpha)}) \), \( \alpha \in [0, 1] \), and the Perron-Frobenius theorem applies to show that they have non-degenerate largest eigenvalues (equal to the operator norm) with eigenvectors that have positive coordinates only. We note that

\[
\text{tr}(K^{di}(g, \alpha)) = \frac{1}{2} \left[ \text{tr}(K(g(1 + \alpha))) + \text{tr}(K(g(1 - \alpha))) \right] = \frac{g(1 + \alpha)}{2(1 - 4g(1 + \alpha))^\frac{1}{2}} + \frac{g(1 - \alpha)}{2(1 - 4g(1 - \alpha))^\frac{1}{2}}
\]

and

\[
\text{tr}(T^{di}(g, \alpha)) = \text{tr}(T(g(1 + \alpha))) + \text{tr}(T(g(1 - \alpha))) = \frac{1 - \sqrt{1 - 4g(1 + \alpha)}}{2\sqrt{1 - 4g(1 + \alpha)}} + \frac{1 - \sqrt{1 - 4g(1 - \alpha)}}{2\sqrt{1 - 4g(1 - \alpha)}}.
\]

For \( g > \frac{1}{4(1+\alpha)} \), it is seen that \( K^{di}(g, \alpha) \) and \( T^{di}(g, \alpha) \) are not bounded operators. By mimicking the analysis of \( D^{\frac{1}{2}} K(g) D^{\frac{1}{2}} \), together with the obvious inequality

\[
|K^{di}_{r,s}(g, \alpha)| \leq K_{r,s}(|g|(|1 + |\alpha|)),
\]

we see that \( D^{\frac{1}{2}} K^{di}(g, \alpha) D^{\frac{1}{2}} \) is analytic in \( (\sqrt{g}, \alpha) \) for \( |\alpha| < 1 \) and \( |g| < \frac{1}{4(1+|\alpha|)} \), taking values in the set of trace-class operators on \( l^2(\mathbb{N}) \).

A slight variation of the argument establishing Lemma 5.2 yields

\[
Z^{di}_m(g, \alpha) \leq \text{tr} \left( T^{di}(g, \alpha)^m \right), \quad m \in \mathbb{N},
\]

for \( g \in (0, \frac{1}{4(1+\alpha)}) \) and \( \alpha \in [0, 1] \). This allows us to establish the following counterpart to Proposition 5.3.

**Proposition 5.4.** For every \( \alpha \in [0, 1] \), the largest eigenvalue \( \lambda_1^{di}(g, \alpha) \) of \( D^{\frac{1}{2}} K^{di}(g, \alpha) D^{\frac{1}{2}} \) is a strictly increasing function of \( g \). As \( g \) approaches \( \frac{1}{4(1+\alpha)} \) from below, its limit \( \lambda_1^{di}(\alpha) \) satisfies

\[
\lambda_1^{di}(\alpha) \leq 1.
\]
Proof. By the variational principle for eigenvalues \( [41] \) and the fact that the matrix elements of \( K^{di}(g, \alpha) \) are strictly increasing functions of \( g > 0 \), one sees that \( \lambda_1^{di}(g, \alpha) \) has a positive derivative with respect to \( g \), and is therefore strictly increasing in \( g \). Suppose the limit in question is greater than 1 for some fixed value of \( \alpha \). Then, there exists a \( g_0 < \frac{1}{4(1+\alpha)} \) such that \( \lambda_1^{di}(g_0, \alpha) = 1 \). A calculation similar to the one leading to (5.10) then implies that

\[
W^{ev}(g, \alpha) = 1 + \sum_{m=1}^{\infty} \langle v(g, \alpha) \mid \left( \frac{1}{2} T^{di}(g, \alpha) \right)^{m-1} \mid v(g, \alpha) \rangle \geq \frac{c'}{1 - \lambda_1^{di}(g, \alpha)} - B(g, \alpha), \quad g \in (0, g_0),
\]

where \( c' > 0 \), while \( B \) is bounded for \( g \) close to \( g_0 \). This shows that \( W^{ev}(g, \alpha) \) diverges as \( g \) approaches \( g_0 \). This, however, contradicts the upper bound in (4.10) with \( k = 1 \), which implies that \( W^{ev}(g, \alpha) \) is bounded for \( g \leq g_0 \).

Since \( T^{di}(g, 0) = 2T(g) \) and \( T^{di}(g, 1) = T(2g) \), Proposition 5.3 implies that

\[
\hat{\lambda}_1^{di}(0) = 1, \quad \hat{\lambda}_1^{di}(1) = \frac{1}{2}.
\]

(5.12)

Our main result on the critical behaviour of the dilute loop model is the following.

**Theorem 5.5.** For \( \alpha \) real and sufficiently small, the critical coupling \( g_c^{di}(\alpha) \) for the partition function \( Z^{di}(g, \alpha) \) is determined by the equation

\[
\lambda_1^{di}(g_c^{di}(\alpha), \alpha) = \frac{1}{2},
\]

(5.13)

and there exist \( C_1(\alpha), C_2(\alpha) > 0 \) such that

\[
\frac{C_1(\alpha)}{g_c^{di}(\alpha) - g} \leq Z^{di}(g, \alpha) \leq \frac{C_2(\alpha)}{g_c^{di}(\alpha) - g} \quad \text{for } g \text{ close to } g_c^{di}(\alpha).
\]

(5.14)

**Proof.** Noting that \( \lambda_1^{di}(g, \alpha) \) is a continuous function, it follows from the first identity in (5.12) that \( \hat{\lambda}_1^{di}(\alpha) > \frac{1}{2} \) for \( \alpha \) sufficiently small. Since \( \lambda_1^{di}(g, \alpha) \) is strictly increasing in \( g \), the intermediate value theorem implies that the value of \( g_c^{di}(\alpha) \) satisfying (5.13) is unique and strictly smaller than \( \frac{1}{4(1+\alpha)} \), for \( \alpha \) small. Thus, \( D^{\frac{1}{2}}K^{di}(g, \alpha)D^{\frac{1}{2}} \) is analytic in a neighbourhood of \( g_c^{di}(\alpha) \) for \( \alpha \) small and fixed.

Mimicking the calculation leading to (5.10) implies that, for \( g \in (0, g_c^{di}(\alpha)) \),

\[
Z^{di}(g, \alpha) \geq \frac{C'_1(\alpha)}{1 - 2\lambda_1^{di}(g, \alpha)} - B(g, \alpha),
\]

where \( C'_1(\alpha) > 0 \), while \( B(g, \alpha) \) is bounded for \( g \) close to \( g_c^{di}(\alpha) \). As previously noted, \( \lambda_1^{di}(g, \alpha) \) is an analytic function of \( g \) in \( (0, g_c^{di}(\alpha)) \). The lower bound in (5.14) follows from the positivity of the \( g \)-derivative of \( \lambda_1^{di}(g, \alpha) \). To obtain the upper bound, we apply (5.11) to write

\[
Z^{di}(g, \alpha) \leq 1 + \sum_{m=1}^{\infty} \text{tr}(T^{di}(g, \alpha))^{m} = 1 + \sum_{m=1}^{\infty} 2^m \text{tr}(D^{\frac{1}{2}}K^{di}(g, \alpha)D^{\frac{1}{2}})^m = 1 + \sum_{n=1}^{\infty} \frac{2\lambda_n^{di}(g, \alpha)}{1 - 2\lambda_n^{di}(g, \alpha)}
\]

for \( g \in (0, g_c^{di}(\alpha)) \), where \( \lambda_1^{di}(g, \alpha) > \lambda_2^{di}(g, \alpha) \geq \lambda_3^{di}(g, \alpha) \geq \ldots \) denote the eigenvalues of \( D^{\frac{1}{2}}K^{di}(g, \alpha)D^{\frac{1}{2}} \). Separating out the first summand, the remaining terms yield a contribution that is bounded for \( g \) close to \( g_c^{di}(\alpha) \), and the upper bound follows as before. This establishes \( g_c^{di}(\alpha) \) as the critical coupling and concludes the proof. \( \square \)
Theorem 5.5 shows that the critical behaviour of $Z^{d_1}(g, \alpha)$ is different from that of the pure CDT model, the exponent characterising the singularity being shifted from $\frac{1}{2}$ to $-1$. For $\alpha = 0$, a more detailed analysis of the corresponding height coupled trees with $k = 2$ carried out in [36] reveals that $Z^{d_1}(g, 0)$ has a simple pole at $g_c^{d_1}(0)$ and that the Hausdorff dimension equals 1. For $\alpha > 0$, such a detailed analysis is not yet available, but Theorem 5.5 provides strong evidence that the singularity is still a simple pole and that the Hausdorff dimension of the disk triangulations underlying the dilute loop configurations equals 1:

$$d_H^{d_1}(\alpha \ll 1) = 1 \quad \text{(almost surely)}.$$  

We have not determined whether the behaviour described by Theorem 5.5 persists for larger values of $\alpha$. By the second identity in (5.12), we note that $g_c^{d_1}(1) = \frac{1}{2}$; in this case, the critical behaviour of $Z^{d_1}(g, \alpha)$ is the same as that of the pure CDT model. Writing the matrix elements of $K^{d_1}(g, \alpha)$ in the form

$$K_{r,s}^{d_1}(g, \alpha) = \frac{1}{2} \frac{(r+s-1)!}{(r-1)!(s-1)!} \left[ 1 + \left( \frac{1-\alpha}{1+\alpha} \right)^{\frac{1}{2}} \right] \left[ 1 + \left( \frac{1-\alpha}{1+\alpha} \right)^{\frac{1}{2}} \right] \left( g(1+\alpha) \right)^{r+s},$$

we see that, for fixed $g(1+\alpha) \in (0, \frac{1}{2})$, they are decreasing functions of $\alpha \in [0, 1]$. It follows that the limiting value $\lambda_1^{d_1}(\alpha)$ is a decreasing function of $\alpha$. Hence, there are two possibilities: either (i) $\lambda_1^{d_1}(\alpha) > \frac{1}{2}$ for all $\alpha \in [0, 1]$, in which case the critical behaviour from Theorem 5.5 extends to $\alpha \in [0, 1]$, or (ii) there exists $\alpha_0 < 1$ such that $\lambda_1^{d_1}(\alpha) > \frac{1}{2}$ for $\alpha \in [0, \alpha_0)$, but $\lambda_1^{d_1}(\alpha) = \frac{1}{2}$ for $\alpha \in (\alpha_0, 1]$. If case (ii) eventuates, the critical behaviour of $Z^{d_1}(g, \alpha)$ for $\alpha \in [\alpha_0, 1)$, in particular at the transition point $\alpha = \alpha_0$, would be an interesting subject of study.

6 Discussion

We have introduced a dense and a dilute loop model on causal triangulations and studied their critical behaviour through examinations of their partition functions and of eigenvalue properties established using a transfer matrix formalism. Both models admit a description in terms of labelled planar trees, but only the dilute loop model experiences an effective height coupling and (for some values of $\alpha$) a change in the Hausdorff dimension. Although the labelled tree correspondences were important in our analysis, it is conceivable that this feature is, in fact, a limitation when it comes to exhibiting nontrivial couplings of matter to geometry.

A natural generalisation of the dilute loop model that does not readily admit a tree correspondence, is obtained by assigning a separate weight to arcs whose endpoints are on the time-like edges of an elementary triangle, as in the second diagrams in Figure 4. With $t(L)$ denoting the number of such arcs in a loop configuration $L \in L_m$, the fixed-height partition functions are given by

$$Z_m^{d_1}(g, \alpha, \gamma) := \sum_{L \in L_m} g^{\|L\|} \alpha^{s(L)} \gamma^{t(L)}.$$

As in the discussion of $Z_m^{d_1}(g, \alpha)$ defined in (2.2), it follows that, for given $\alpha, \gamma \in [0, 1]$, there exists a critical coupling $g_c^{d_1}(\alpha, \gamma)$ such that $Z_m^{d_1}(g, \alpha, \gamma)$ is finite for $g < g_c^{d_1}(\alpha, \gamma)$ and divergent for $g > g_c^{d_1}(\alpha, \gamma)$. Since $Z_m^{d_1}(g, \alpha, \gamma) \leq Z_m^{d_1}(g, \alpha, 1) = Z_m^{d_1}(g, \alpha)$, we see that

$$g_c^{d_1}(\alpha, \gamma) \geq g_c^{d_1}(\alpha, 1) = g_c^{d_1}(\alpha).$$

Attributing a unity of length to each arc, one may view $s(L) + t(L)$ as the total length of $L$. For $\gamma = \alpha$, the weight of a loop configuration can thus be expressed in terms of area and length, in the sense noted for the dense loop model at the end of Section 2.2. On the other hand, the tree correspondence of Proposition 3.6 is seen to introduce long-distance couplings on the trees, thereby limiting its usefulness in this case. Related to this, it is not possible to perform the summation over loop labellings and triangulations independently in [0,1], as was done in the dense and dilute models. This intimate connection between
matter and geometry is an interesting yet challenging aspect of this new model. A fully-packed version of the dilute loop model, where empty triangles are excluded, can be obtained as a limiting case of the generalised dilute loop model described above and will likewise exhibit long-distance tree couplings.

It would also be interesting to study the dense and dilute loop models with loop fugacities different from 1 and to explore other types of loop models on causal triangulations. For example, one may adapt the so-called fused Temperley-Lieb loop models \cite{43,44,45} based on \cite{46,47}, and loop models whose underlying algebraic structures are given by Birman-Wenzl-Murakami algebras \cite{48,49}. We anticipate that one may describe and analyse such models, including partition functions and correlation functions more generally, using an extension of the transfer matrix formalism employed in Section 5.
