Keywords: apoplastic barrier, exodermis, flooding, lignin, phytotoxins, radial O₂ loss (ROL), suberin, waterlogging.

Summary

- The root barrier to radial O₂ loss (ROL) is a key root trait preventing O₂ loss from roots to anoxic soils, thereby enabling root growth into anoxic, flooded soils.
- We hypothesized that the ROL barrier can also prevent intrusion of hydrogen sulphide (H₂S), a potent phytotoxin in flooded soils. Using H₂S- and O₂-sensitive microsensors, we measured the apparent permeance to H₂S of rice roots, tested whether restricted H₂S intrusion reduced its adverse effects on root respiration, and whether H₂S could induce the formation of a ROL barrier.
- The ROL barrier reduced apparent permeance to H₂S by almost 99%, greatly restricting H₂S intrusion. The ROL barrier acted as a shield towards H₂S; O₂ consumption in roots with a ROL barrier remained unaffected at high H₂S concentration (500 μM), compared to a 67% decline in roots without a barrier. Importantly, low H₂S concentrations induced the formation of a ROL barrier.
- In conclusion, the ROL barrier plays a key role in protecting against H₂S intrusion, and H₂S can act as an environmental signalling molecule for the induction of the barrier. This study demonstrates the multiple functions of the suberized/lignified outer part of the rice root beyond that of restricting ROL.

Introduction

Plant growth in flooded, anoxic soils relies on several key root traits with the barrier to radial O₂ loss (ROL) being one of the most important. The root barrier ROL consists of suberized and sometimes lignified (Ranathunge et al., 2011a) exodermal cells restricting O₂ diffusion to the soil and retaining O₂ within the root (Watanabe et al., 2013). O₂ diffuses longitudinally towards the root tip following a concentration gradient and enables cell division and continued root extension that only takes place in the presence of molecular O₂ (Armstrong & Webb, 1985; Colmer, 2003a). Here, we show that the ROL barrier also restricts radial H₂S intrusion, thereby protecting the root tissue from this potent soil phytotoxin. We also show that low and non-lethal concentrations of H₂S act as an environmental signal for the ROL barrier formation through upregulations of genes related to lignin rather than suberin biosynthesis.

Roots of wetland plants rely on longitudinal diffusion of O₂ from the shoot to the root tips when growing in flooded soils. Flooded soils are generally anoxic since molecular diffusion in water is too slow to replenish O₂ consumed by plant roots and soil microbes (Colmer & Voesenek, 2009), and roots cannot rely on radial supply of O₂ from the rhizosphere. Instead, longitudinal diffusion of O₂ is facilitated via gas-filled spaces (aerenchyma) providing a low resistance pathway for gas diffusion (Yamauchi et al., 2019). Roots of rice constitutively form aerenchyma (Shiono et al., 2011) in drained soils, helping the existing roots survive should soil flooding occur. Nevertheless, additional aerenchyma is induced as a response to soil flooding, further enhancing the capacity for internal aeration (Pedersen et al., 2020). While a large proportion of the O₂ diffusing towards the root apex is radially lost into the anoxic rhizosphere, ROL can be significantly restricted by a barrier to ROL (Kotula et al., 2009), thereby extending the maximum root length achieved in flooded soils (Jiménez et al., 2020).

The formation of the ROL barrier can be induced by several environmental cues. Soil flooding in itself is able to induce a formation of the ROL barrier (Colmer, 2003b); although abscisic acid is involved in the ROL barrier formation (Shiono et al., 2022), the exact mechanisms behind it remain unclear. Neither low O₂, high CO₂ nor ethylene acts as signals for the ROL barrier formation in rice (Colmer et al., 2006), whereas several of the phytotoxins produced by soil microbes in flooded soils have been shown to induce ROL barrier formation, namely low-molecular weight carboxylic acids (Colmer et al., 2019) and Fe²⁺ (Mongan et al., 2014). Interestingly, high concentrations of sulphides can further enhance the tightness of an existing ROL barrier (Armstrong & Armstrong, 2005), but it is not known whether low and non-lethal concentrations of H₂S can also act as an environmental cue for the ROL barrier.
Histochemically, the root ROL barrier consists of enhanced cell wall depositions of suberin and lignin in the exodermis. While the exodermis can also be lignified (Ranathunge et al., 2011b), it is hypothesized that the gas-tight feature of the exodermis is primarily due to the suberization (De Simone et al., 2003; Nishiuchi et al., 2012). In accordance with this hypothesis, upregulation of genes involved in suberin biosynthesis is observed when roots of rice are exposed to the relevant environmental signals (Shiono et al., 2014), whereas upregulation of lignin-related genes is seen as a stress response once the signalling compounds are supplied in high concentrations (Colmer et al., 2019).

A true jack of all trades, the root barrier to ROL not only restricts radial diffusion of molecular O₂ but also diffusion of other gases and even movements of ions through the apoplast. The ROL barrier greatly restricts radial diffusion of H₂ (Peralta Ogorek et al., 2021), even if molecular H₂ is a much smaller molecule compared to O₂ and, therefore, diffuses faster (Zhang & Cloud, 2006). Furthermore, radial diffusion of water is likewise restricted, sparking speculations that the ROL barrier is possibly of importance as a drought tolerance trait (Peralta Ogorek et al., 2021), and it has been shown that low water potentials can induce a ROL barrier in roots of rice (Song et al., 2023). Finally, radial movement of solutes via the apoplast is also restricted by the ROL barrier; the permeability to NaCl decreased by 60% compared to that in roots without a barrier (Ranathunge et al., 2011a). When supplied with reduced iron, Fe²⁺ mostly accumulated exteriorly to the exodermis in mature regions of the roots where a ROL barrier was formed, whereas Fe²⁺ was localized also in the cortex and endodermis in the root tip region where the barrier is not formed (Jimenez et al., 2021). Consequently, it has been suggested that the ROL barrier could also restrict H₂S diffusion into the roots (Armstrong & Armstrong, 2005; Soukup et al., 2007; Nishiuchi et al., 2012), but although H₂S can be an important phytotoxin in some soils, this hypothesis remained untested.

H₂S is a potent phytotoxin present in anoxic, acidic flooded soils. H₂S is produced by anaerobic sulphate-reducing bacteria using sulphate as electron acceptor (Lamers et al., 2013), and acts similarly to cyanide by inhibiting the cytochrome c oxidase at concentrations of 1–10 μM (Raven & Scrimeour, 1997; Armstrong & Armstrong, 2005). H₂S does not require any facilitator to diffuse through the lipid bilayer cell membrane and can diffuse as fast as O₂ or CO₂ despite the fact that H₂S is a polar molecule that can form hydrogen bonds (Riahi & Rowley, 2014). Once H₂S permeates inside the root tissue, it quickly diffuses though the aerenchyma (Pedersen et al., 2004), and even though H₂S is spontaneously oxidized by O₂, the oxidation rate is slow without the aid of H₂S-oxidizing bacteria (Pedersen et al., 2004). Furthermore, H₂S in the soil has been linked to a disease in rice called ‘Straighthead’ that reduces rice productivity (Joshi et al., 1975; Lamers et al., 2013), making this phytotoxin of great economic interest. This suggests that H₂S could diffuse through the root aerenchyma, all the way to the shoot, and cause the disease.

We aimed at closing the long-standing knowledge gaps related to the role of H₂S signalling for ROL barrier formation as well as the putative capacity of the ROL barrier to restrict H₂S intrusion. We tested the hypothesis that the ROL barrier restricts H₂S intrusion into roots of rice using H₂S-specific microelectrodes to obtain the permeance to H₂S of the outer part of the roots without or with a ROL barrier. Moreover, we measured H₂S intrusion on intact roots while manipulating the O₂ supply from the shoot to the roots since root O₂ status was shown to be an important factor to prevent H₂S intrusion into seagrass roots (Borum et al., 2005). We also tested the toxicity of H₂S on respiration in roots with or without a ROL barrier and established a dose–response curve for tissue toxicity. Finally, we investigated the role of low and non-lethal concentrations of H₂S as a signal for the ROL barrier formation and evaluated upregulated and downregulated key genes involved in suberin and lignin biosynthesis during H₂S exposure.

Materials and Methods

The following sections conceptually describe the experimental procedures (see Supporting Information Methods S1 for details).

Plant material

Seeds of rice (Oryza sativa L.) genotype ‘IR42’, a moderate drought and submergence tolerant cultivar (Ponnamperuma, 1979), were germinated and grown in hydroponics without (nutrient solution with forced aeration using air pumps) or with a ROL barrier (7 d in stagnant, deoxygenated nutrient solution) as described in Peralta Ogorek et al. (2021). Plant age during measurements ranged between 26 d to 36-d-old, except for plants with a weak barrier, which was induced by growing plants in aerated nutrient solution for 44–55 d.

O₂ or H₂S flux into root segments

Fluxes of O₂ or H₂S into root segments were used to assess the presence or absence of a ROL barrier (O₂ intrusion) or to evaluate the capacity of the barrier to ROL to restrict H₂S intrusion; see Peralta Ogorek et al. (2021; Fig. 1a) for details on the experimental setup. Segments from position 30–60 mm behind the root tip were prepared from target roots without or with a ROL barrier. The segments had their cut ends sealed with lanolene to prevent gas intrusion via the cut ends, and were fixed on a metal mesh using rubber bands. The mesh was placed inside an aquarium, where an O₂ or H₂S microsensor was inserted 150–250 μm into the root cortex. Solutions with specific composition of O₂ or H₂S (<60 kPa pO₂/c: 0.04 or 0.22 kPa pH₂S) were added to the aquarium and gas intrusion into the cortex was recorded. Measurements lasted a minimum of 15–20 min or until a quasi steady state was achieved (O₂ or H₂S readings in the cortex changed < 5% per 5 min). The intrusion rate of O₂ was calculated from the linear slope when the cortex reached air equilibrium (20.6 kPa). For H₂S, the intrusion rate was calculated when 50% of the quasi steady state of pH₂S inside the root cortex was obtained.

The intrusion rates were used to calculate the apparent permeance (Pm, m s⁻¹) to O₂ or H₂S following the equation described in Lendzian (2006):

\[
P_m = \frac{\text{flux}}{\text{concentration difference}}
\]
Research 1827

Hydrogen sulphide intrusion into root segments of rice (Oryza sativa) is greatly restricted by the barrier to radial oxygen loss (ROL). Panel (a) shows a time trace of H2S intrusion into root segments from 26- to 36-d-old plants without (aerated nutrient solution) or with (stagnant, deoxygenated nutrient solutions) a barrier to ROL when exposed to pH2S 0.04 or 0.22 kPa. The segments representing position 30–60 mm behind the root tip were prepared from 10 to 14 cm long roots which had the root tip removed and cut ends sealed with lanoline. The segments were then positioned on a metal mesh and had a H2S microsensor inserted 150–250 μm into the cortex to follow the cortical pH2S; external pH2S was measured with another H2S microsensor. The intrusion rates were used to calculate the apparent permeance (P) to H2S, shown as a box-whisker plot (b; mean, +; median, horizontal line; 50% quartiles, box; minimum and maximum values, whisks), where n = 4–5 without a barrier and n = 5–7 with a barrier. Comparisons between segments were conducted using a two-way ANOVA followed by a Tukey test (****, P ≤ 0.0001) on log-transformed data.

\[ P_a = \frac{F}{A \times \Delta C} \]

where \( F \) (mol s\(^{-1}\)) is the intrusion rate of O2 or H2S, \( A \) (m\(^2\)) is surface area of the root segments and \( \Delta C \) (mol m\(^{-3}\)) is the concentration gradient between the cortex and the external solution.

H2S intrusion in intact roots attached to the shoot

These measurements served to mimic a natural situation where molecular O2 diffuses via the aerenchyma from the shoot to the roots so that O2 is present inside the root tissue. O2 can oxidize H2S to non-toxic compounds (S\(^0\) or SO\(_4^{2-}\)) and thereby reduce tissue O2 levels when the root is exposed to H2S in a soil environment. Moreover, the root tip can act as a window for H2S intrusion since a barrier to ROL is never formed close to the root tip (Colmer, 2003b).

Experiments were conducted using tillers with one target root. The root was mounted and fixed on a metal mesh and placed into a two-compartment chamber separating the root from the shoot, after which an O2 and a H2S microsensor were inserted into the root cortex 2–3 cm below the root–shoot junction. The root compartment was filled with a stagnant solution and then cortex O2 status was measured in the absence of H2S. Then, the root chamber was drained, and the liquid replaced with a stagnant solution now containing 0.18–0.22 kPa pH2S to follow H2S intrusion with the shoot either in air or submerged to facilitate or restrict O2 diffusion from the shoot to the root.

H2S toxicity measured as impact on respiration

We assessed the toxicity of H2S on respiration of root segments without or with a ROL barrier measured as O2 consumption. We also measured the respiration of root tips to obtain a toxicity curve and estimate the EC50 of H2S.

Target roots without or with a barrier were shortened to 50 mm segments, had the apical 30 mm removed, and their cut ends sealed with lanoline. They were then incubated in a solution without (control) or with 500 μM H2S for 4 h. Afterwards, the segments were rinsed, split open through the middle (Jiménez et al., 2020), left to acclimate for 15 min covered with moist paper towel, and finally placed inside glass vials with DI water at air equilibrium; see Results section for justification of the splitting approach. For root tip respiration measurements, target roots were incubated in various concentrations of H2S for 4 h after which the most apical 10–12 mm were excised from the roots, rinsed in DI water, and placed inside glass vials with DI water at air equilibrium. An O2 minioptode was inserted into the vials to measure the decline of O2 over time to calculate respiration rates expressed by unit of fresh mass.

The effect of splitting the roots was also tested by incubating target roots without or with a barrier to ROL for 1 h in DI water saturated with air. The procedure was as described earlier, except a group of segments were split before placing them inside the vials, or directly placed in the vials without splitting.

Root elongation rates in the presence or absence of H2S

We measured the elongation rates of roots without H2S (control) or with H2S in the nutrient solution. Plants without a barrier to ROL were exposed to 10–20 μM H2S (EC50 concentration of root tip – see the Results section) by purging the nutrient solution with a mixture of air and H2S. The H2S concentration in the nutrient solution was constantly monitored using H2S microsensors.

Target roots were tagged to follow their growth during 5 d of H2S exposure, and the elongation rate was calculated from daily measurements of the tagged roots. After 5 d, the purging of H2S was stopped, the nutrient solution renewed, and was only aerated with air. New roots were tagged, and their elongation followed to
measure roots elongation in the recovery phase. Finally, elongation rates were also followed on new adventitious roots that formed from primordia during the recovery phase.

Induction of a ROL barrier by H₂S

Several environmental signals have been shown to trigger the ROL barrier formation in rice. Therefore, we tested whether low concentrations of H₂S could induce a ROL barrier. Plants without a barrier to ROL were moved into a nutrient solution purged with a mixture of air and H₂S (10–20 μM H₂S, see earlier). Another group of plants were transferred to stagnant nutrient solution to serve as a benchmark for the ROL barrier formation. Target roots were harvested to conduct O₂ intrusion measurements on segments to calculate Pₑ to O₂ (see ‘O₂ or H₂S flux into root segments’ in the Materials and Methods section) to monitor the barrier formation with time.

Gene expression during ROL barrier formation by H₂S

Root segments from plants of the same age growing in aerated conditions and 24 h after being transferred into H₂S or stagnant nutrient solutions were harvested and fixed in 100% methanol. The segments were embedded in paraffin (Takahashi et al., 2010) and laser microdissection (LM) was used to obtain serial cross-sections of 12 μm thickness. Total RNA was extracted from the LM-isolated tissues, and the quality of the RNA was assessed as described by Takahashi et al. (2010). RNA sequencing was performed at MacroGen Inc. (www.macrogen.com) using NovaSeq6000. After constructing the gene libraries, STAR (Dobin et al., 2013) was used to map a single-end read to the reference rice genome, which was downloaded from the PHOTOTOME v.13 database (https://phototome-next.jgi.doe.gov). Differentially expressed genes were extracted using DESEQ2 (Love et al., 2014) between aerated and stagnant or H₂S conditions, selecting genes that showed greater than twofold change in read counts. Information on gene annotation in rice and homologous genes in Arabidopsis thaliana were downloaded from PHOTOTOME v.13. Finally, gene ontology (GO) enrichment analysis was performed with SHINYGO (http://bioinformatics.sdstate.edu/go/), selecting biological processes of GO terms with an enrichment false discovery rate (FDR) < 0.01.

Histochemical staining of lignin and suberin in cell walls

To visualize the modifications of the cells related to the ROL barrier, histochemical staining of lignin and suberin was conducted on root segments from aerated, stagnant or H₂S-exposed conditions. Lignin depositions were detected using phloroglucinol (Jensen, 1962) or the Maule reaction (Kutscha & Gray, 1972). Cinnamaldehyde and syringil groups stain red–pink and brown–orange–pink, respectively, under white light. Suberin depositions in cell walls were detected using Fluorol Yellow 088 solution under UV light (Brundrett et al., 1991). To facilitate the interpretation of suberin patterns, we calculated the percentage of suberized cell and tested these with a one-way ANOVA.

Statistical analyses

GraphPad Prism software (v.8.4.3) was used to plot and analyse the data, except GO enrichment analysis that was conducted with SHINYGO (http://bioinformatics.sdstate.edu/go/). The statistical analyses conducted for each experiment are detailed in the corresponding figure captions, together with number of replicates and significance levels. Pₑ to H₂S on root segments and percentage of suberized cells was log-transformed to improve data homoscedasticity and normality. For all figures, non-transformed data are shown.

Results

H₂S intrusion into root segments

In addition to O₂, the ROL barrier restricts radial diffusion of gaseous H₂ and H₂O (Peralta Ogorek et al., 2021). Therefore, we tested whether the ROL barrier prevents intrusion of H₂S into the root when exposed to 0.04 or 0.22 kPa pH₂S. Cortical H₂S of segments without a barrier surged and reached quasi steady state within a few minutes of exposure, indicating a very low resistance to radial H₂S diffusion (Fig. 1a). By contrast, segments with a barrier showed high resistance to radial diffusion of H₂S. For the first c. 50 min at 0.04 kPa, there was no detectable intrusion, whereas cortical H₂S slowly increased but rarely exceeded 0.01 kPa after 90 min of exposure. Similarly, with pH₂S of 0.22 kPa, there was a long lag phase with cortical H₂S below the detection limit (c. 20 min), after which H₂S intrusion occurred faster than when exposed to 0.04 kPa (Fig. 1a).

Rates of H₂S intrusion were converted into apparent permeance (Pₑ) to H₂S to correct for differences in intrusion rates due to variations in root thickness and concentration gradients. Mean Pₑ to H₂S for roots without a barrier was 2.50 × 10⁻⁶ m² s⁻¹, being 75-fold higher than for roots with a barrier, which had a mean Pₑ of 3.34 × 10⁻⁸ m² s⁻¹ (Fig. 1b). These results show that the ROL barrier in the outer part of the root cannot entirely prevent H₂S intrusion but greatly restricts radial intrusion.

H₂S intrusion into intact roots

We mimicked a natural situation where roots have a constant supply of O₂ diffusing from the aerial parts via the aerenchyma to the root tip. Here, the internal molecular O₂ has the potential to oxidize H₂S. Moreover, the root tip represents a window without a ROL barrier where H₂S may enter and thereby bypass the ROL barrier present further up the root axis. H₂S and O₂ micro-sensors were inserted simultaneously into the cortex 3 cm below the root shoot junction (Fig. 2a). First, the O₂ status was assessed with the roots submerged into a stagnant (deoxygenated) solution without H₂S, and the cortical pO₂ remained constant at c. 15 kPa. Next, the root medium was replaced with a stagnant solution containing 0.18–0.22 kPa pH₂S. The intrusion of H₂S into intact roots without a barrier was fast and reached quasi steady state within few minutes (Fig. 2b), and cortical O₂ was not affected by H₂S. The cortical pH₂S remained almost constant.
throughout the measurements, even when the shoot was submerged to restrict O₂ supply to the roots. After the shoot was de-submerged and O₂ supply to the roots was re-established, pH₂S in the cortex remained unaffected showing that there was little spontaneous oxidation of H₂S inside the cortex.

Intrusion of H₂S into roots with a ROL barrier showed a different pattern (Fig. 2c). There was a long lag phase where H₂S was below detection limit, whereafter H₂S increased at a slower pace than for isolated root segments with similar external pH₂S. When the shoot was submerged, there was a small increase in H₂S intrusion, and when the shoot was de-submerged, pH₂S again declined slightly (Fig. 2c). Direct comparison of pO₂ and pH₂S revealed that the O₂ status was similar for roots with or without a barrier to ROL at the root–shoot junction, whereas the cortical pH₂S of roots without a barrier was sevenfold higher than in roots with a barrier (Fig. 2d).

Influence of H₂S on root respiration and growth

H₂S impacts mitochondrial respiration in a similar way to cyanide (Raven & Scrimgeour, 1997), and we therefore tested whether the slower intrusion rates observed in roots with a barrier to ROL would also show reduced effects on root respiration. Root segments without or with a barrier were incubated in 500 μM H₂S, and after exposure to H₂S the segments were cut longitudinally to expose respiring tissue since the barrier would prevent radial O₂ diffusion and, thus, respiration. The possible effect on root respiration caused by splitting the roots was tested, but with no significant effect on tissue splitting (Fig. S1). As hypothesized, H₂S greatly reduced O₂ respiration in segments without a ROL barrier and respiration was threefold higher in controls than segments exposed to H₂S (Fig. 3a). Importantly, respiration of segments with a barrier was not at all affected by exposure to 500 μM H₂S, which is 50- to 500-fold the established level for impact at the cytochrome c level.

Root tips do not form a ROL barrier, and it is therefore relevant to determine the toxicity of H₂S on root tips since these hold the root meristem. We measured respiration of detached root tips after exposure to H₂S concentrations ranging from 0 to 500 μM (Fig. 3b). The respiration rate of root tips showed a typical dose–response relationship and the EC₅₀ was estimated to be 15 μM. The respiration continued to decline with increasing...
Fig. 3. Hydrogen sulphide toxicity in root segments of rice (Oryza sativa) is reduced by the barrier to radial oxygen loss (ROL). Panel (a) shows the respiration rate of root segments from 26- to 36-d-old plants without (aerated nutrient solution) or with (stagnant, deoxygenated nutrient solutions) a barrier to ROL as a box whisker plot (mean, +; median, horizontal line; 50% quartiles, box; minimum and maximum values, whiskers), where n = 4 for without or with barrier. Roots 10–14 cm had the most apical 3 cm removed and shortened to 8 cm segments, whereas the cut ends were sealed with lanolin and incubated in 500 μM H2S for 4 h. The segments were then further shortened to 32 mm and split open through the middle with a razor blade before starting the respiration measurements. The respiration rates were compared using a two-way ANOVA followed by a Tukey test (***, P < 0.001; ns, non-significant). Panel (b) shows the respiration rates of root tips (black dots, mean; vertical lines, SD; horizontal lines, concentration range; black line, non-linear curve fit), where n = 4 for all concentrations. Roots 10–14 cm long were severed and incubated in the different H2S concentrations for 4 h. Afterwards, the most apical 10–12 mm were cut and used for respiration measurements. All respiration measurements were conducted in a constant temperature bath at 25°C. EC50 = 15 μM or 0.013 kPa pH2S and 500 μM H2S = 0.46 kPa pH2S. Panel (c) shows the elongation rate of roots without a barrier growing in aerated conditions (aerated controls) and aerated conditions with constant H2S purge (10–20 μM; H2S-exposed) as a box whisker plot (mean, +; median, horizontal line; 50% quartiles, box; minimum and maximum values, whiskers), where n = 5 for all conditions. Elongation was measured every day for 4–5 d on roots with a starting length of 3–5 cm. The elongation rates were compared using a one-way ANOVA (**, P ≤ 0.01; ns, non-significant).

H2S acts as an environmental signal for ROL barrier formation

It has been shown that the barrier formation was accelerated after exposing roots growing in stagnant conditions coupled with high concentrations of H2S (Armstrong & Armstrong, 2005), but it was not known whether H2S in itself could induce barrier formation. We therefore assessed the barrier formation over time using Pa to O2 as a diagnostic tool for roots growing in an aerated nutrient solution without or with H2S, or in stagnant nutrient solution. We found an identical pattern of barrier formation regardless of the treatment (Fig. 4a), and already after 12 h, Pa to O2 declined in both treatments. However, it was only after 48 h of treatment that Pa had declined significantly in both H2S and stagnant conditions; Pa to O2 in controls were 2.5- and 3.0-fold higher than in H2S-exposed and stagnant conditions, respectively.

concentrations up to 135 μM, whereafter the respiration did not decline beyond 0.23 nmol O2 g−1 FM s−1.

Following the observation that H2S strongly affected the respiration of root tips, we measured how H2S toxicity affected root elongation. We purged the nutrient solutions with a mixture of air and H2S resulting in 10–20 μM H2S, that is the EC50 for root tip respiration. Root elongation was significantly reduced, and roots of control plants grew twofold faster than roots of plants exposed to H2S (Fig. 3c). Some H2S-exposed roots completely stopped growing while most roots kept growing but at a slower pace, and on the average the elongation rates were reduced by 52%. Interestingly, a recovery experiment showed that some roots exposed to H2S generally resumed growth once H2S had been removed from the medium, but these never obtained rates similar to pre-exposure conditions (Fig. S2). Instead, adventitious roots were formed several days after H2S exposure and these had elongation rates similar to pre-exposure conditions, indicating that the root primordia had not been irreversibly damaged by H2S.

These results clearly show that the ROL barrier can prevent H2S toxicity, and that H2S toxicity did not completely stop root growth when H2S is supplied at levels equivalent to EC50 for root respiration. In fact, roots were able to partly recover from exposure to H2S concentration at around EC50 and the root primordia remained unaffected, allowing the formation of new adventitious roots following the exposure to H2S.
Beyond 48 h, \( P_a \) to \( O_2 \) of \( H_2S \)-exposed roots did not decline, indicating that the barrier was not further strengthened.

**Gene expression during ROL barrier formation**

Since the ROL barrier was formed in response to both \( H_2S \) and stagnant treatments, a shared gene network between the two conditions likely exists. Therefore, we performed RNA-seq analysis on tissues from the outer part of the root using LM on roots grown in the aerated nutrient solution without or with \( H_2S \), or in stagnant solution. Compared to aerated conditions, we found that 1694 and 114 \( < \) 7 genes were upregulated (Fig. 5a; Tables S1, S2), while 2084 and 1271 genes (Fig. 5b; Tables S3, S4) were downregulated for \( H_2S \) and stagnant treatments, respectively. This clearly reveals a more extensive response to \( H_2S \)-exposed compared to stagnant conditions. From these, 276 genes were commonly upregulated and 385 genes downregulated between \( H_2S \) and stagnant treatments (Table 1). Similarly, GO terms related to lignin biosynthesis (e.g. 'regulation of lignin biosynthetic process', 'lignin biosynthetic process', 'lignin metabolic process') or related to both suberin and lignin biosynthesis (e.g. 'phenylpropanoid biosynthetic process' and 'phenylpropanoid metabolic process') were significantly enriched in commonly upregulated genes under both \( H_2S \) and stagnant treatments. Moreover, 11 genes were commonly upregulated in both \( H_2S \) and stagnant treatments and classified into phenylpropanoid and/or lignin metabolic processes (Table 1).
of several catabolic processes like ‘leucine catabolic process’ were enriched among the downregulated genes under both H₂S and stagnant treatments (Fig. 6b).

Suberin might be a key component of the ROL barrier, but we only found patchy depositions in the cell walls (see later). Interestingly, LOC_Os08g44360 encoding fatty acid reductase (FAR) and LOC_Os11g31090, a homolog gene of REDUCED LEVELS OF WALL-BOUND PHENOLICS 1 (RWP1) in Arabidopsis, were upregulated in both H₂S and stagnant conditions (Table 1). Moreover, we found that different copies of suberin biosynthesis genes were upregulated under H₂S and stagnant conditions. One copy of 3-ketoacyl-CoA synthases (KCS), involved in fatty acid elongation, was significantly upregulated under H₂S conditions, and other four copies were upregulated under stagnant conditions (Table S7). Similarly, one copy of glycerol-3-phosphate acyltransferase (GPAT) was significantly upregulated under H₂S conditions, and other two copies were upregulated under stagnant conditions (Table S7). Finally, one copy of CYP86A, involved in fatty acid oxidation, was upregulated under stagnant conditions (Table S7).

Table 1 Commonly upregulated genes of rice (Oryza sativa) roots from 26- to 36-d-old plants grown in aerated conditions with hydrogen sulphide or in stagnant, deoxygenated conditions, classified into phenylpropanoid and/or lignin metabolic process.

Fig. 6 Gene ontology (GO) term enrichment analysis of commonly upregulated or downregulated genes between roots of rice (Oryza sativa) grown in aerated conditions with hydrogen sulphide or in stagnant, deoxygenated conditions revealed predominant enrichment of lignin-related terms. Panels (a, b) show the GO terms enriched in the upregulated or downregulated expressed genes, respectively, shared between the outer parts of the root from 26- to 36-d-old plants grown in aerated conditions with H₂S or in stagnant, deoxygenated conditions for 24 h. Fisher’s exact test was applied to identify the most enriched GO terms. Larger circles in the hierarchical clustering trees represent more genes annotated to the respective GO terms. The right-hand colour bars indicate P values (< 0.05); n = 4 for all.
Histochemical staining of lignin and suberin

We characterized the ROL barrier using histochemical staining, detecting lignin and suberin depositions in the cell walls (Fig. 7). Lignin staining revealed cinnamaldehyde and syringil depositions in aerated controls throughout the sclerenchyma layer (Fig. 7a,d). However, roots exposed to H$_2$S showed a distinct pattern: cinnamaldehyde and syringil lignin depositions intruded between the exodermal cells above the sclerenchyma (Fig. 7b,e). Moreover, the coloration of lignin staining appeared to be slightly stronger in roots exposed to H$_2$S in the part of the sclerenchyma immediately inside of the exodermal cells compared to the part facing the cortex. Cinnamaldehyde depositions were also detected enveloping some exodermal cells (Fig. 7b). For stagnant-grown roots, both lignin groups were evenly stained in the sclerenchyma, with slightly less lignin intrusion between the exodermal cells compared with that of roots exposed to H$_2$S (Fig. 7c,f).

Suberin staining was also detected in roots of all three growth conditions showing a 'patchy' deposition pattern as some cells were suberized, whereas others were not (Fig. 7g–i). Accordingly, quantitative comparison of suberin depositions under the three growth conditions showed no significant differences in the percentage of suberized cells in the exodermis (aerated, 34.5 $\pm$ 0.07%; aerated+H$_2$S, 31.7 $\pm$ 0.04%; stagnant, 53.0 $\pm$ 0.16%; mean $\pm$ SE; $n = 4$).

Discussion

Hydrogen sulphide is known as a potent phytotoxin and it has long been debated whether the root barrier to ROL can restrict radial diffusion of H$_2$S from flooded soils into the root tissue, but this hypothesis had never been tested. We found that the ROL barrier greatly restricts H$_2$S intrusion, and thereby root respiration remained unaffected even at very high external H$_2$S concentrations. We also showed that low concentrations of H$_2$S act as a signal for the ROL barrier formation. Below, we discuss these findings in detail, including the genes involved in the formation of the ROL barrier when exposed to H$_2$S or stagnant conditions.

The ROL barrier reduced intrusion of H$_2$S

We evaluated whether the ROL barrier would restrict H$_2$S intrusion from the rhizosphere. We found that the barrier decreased apparent permeance ($P_a$) to H$_2$S by almost 99% (Fig. 1b), clearly demonstrating the protective role of the ROL barrier. In
comparison, a tight barrier virtually blocks O₂ intrusion, whereas the reduction in Pₚ to H₂ or water vapour by the barrier is comparatively lower (reduced by 74% and 94%, respectively, Peralta Ogorek et al. (2021)). We therefore propose that the evolutionary role of the barrier is not only restricted to prevent ROL, but also serves a protective role against soil phytophotoxins intrusion, now shown for H₂S and also for reduced Fe (Jiménez et al., 2021).

Interestingly, shoot O₂ supply and internal aeration had little influence on H₂S intrusion in intact roots (Fig. 2b,c). This is different to seagrasses, where a reduction in O₂ supply to the shoot accelerated H₂S intrusion into the belowground tissues (Pedersen et al., 2004; Borum et al., 2005; Brodersen et al., 2017). However, roots growing in hydropicnons are unlikely to form a stable biofilm hosting H₂S-oxidizing bacteria, and such bacteria greatly increase H₂S oxidation in the presence of O₂ (Pedersen et al., 2004); these biofilms would likely establish in paddy soils just like in seagrass sediments (Brodersen et al., 2015). Importantly, a radial flux of O₂ to the rhizosphere can be beneficial and act as a means of detoxification when H₂S is oxidized to SO₄^{2−}, a process that also reduces the formation of Fe₃S plaques; such plaques hamper nutrient uptake in wild rice (LaFond-Hudson et al., 2018). Regardless, during flood events where the entire shoot becomes submerged, reduced O₂ supply to the roots occurs during nighttime (Pedersen et al., 2009; Winkel et al., 2013), and this could lead to critically high tissue H₂S concentrations since we do observe a slight acceleration in H₂S intrusion when shoot O₂ supply is restricted, even in our short-term experiments.

Toxic effects of H₂S on root respiration and elongation

The presence of the ROL barrier significantly reduced the toxic effect of H₂S. We used a new approach enabling root respiration measurements in the presence of a ROL barrier (Jiménez et al., 2020) and found that the respiration rates of segments without a barrier were reduced by 67% at 500 μM of H₂S. In comparison, 380–480 μM (undissociated) of four different types of low molecular mass organic acids reduced O₂ consumption by only 22% (Colmer et al., 2019) demonstrating the high toxicity of H₂S (Raven & Scrimgeour, 1997). Importantly, a tight barrier restricted H₂S intrusion so that even at 500 μM external concentration, the respiration remained unaffected, whereas a weak barrier resulted in some decline in tissue respiration (Fig. S3).

Root tips do not form a ROL barrier and root tip respiration is essential for root elongation (Armstrong & Beckett, 1987). Our dose–response experiment revealed an EC₅₀ of root tip respiration of 15 μM H₂S (Fig. 3b), which is substantially lower than that of organic acids, being in the mM range (Colmer et al., 2019). A low EC₅₀ would be expected considering that mitochondrial function is impacted already at concentrations between 1 and 10 μM (Raven & Scrimgeour, 1997). Physiological function is also impacted as evidenced by a reduction of 80% in phosphorous uptake for four rice cultivars when exposed to 15 μM of H₂S (Joshi et al., 1975). There was some residual O₂ consumption even at the highest concentration used, so we tested the effect of incubation time and found that the residual respiration declined significantly from 2 to 4 h (the latter was used in Fig. 3b). Therefore, we cannot rule out that the residual respiration would decline further with even longer incubation times.

The physiological impact of H₂S on root tips was clearly demonstrated in this study by the reduction in root growth. The reduction in root elongation (Fig. 3c) corresponded closely to the EC₅₀; a 50% reduction in O₂ consumption also resulted in halving of the root elongation rate. A previous study showed that much higher H₂S concentrations (174 μM) completely stunned root growth (Armstrong & Armstrong, 2005). This past study also showed that root growth resumed when H₂S was removed from the nutrient solution. In this study, there was a tendency of recovery of the H₂S-exposed roots within 4 d (Fig. 3c) showing that the damage at the mitochondrial level is severe close to the EC₅₀, but new adventitious roots emerged after the H₂S exposure and grew at similar rates to that of the control plants (Fig. S2), demonstrating that the root primordia had not been damaged. However, we did not test whether the significant restriction in H₂S intrusion caused by the presence of the ROL barrier was beneficial at the whole plant level (root elongation or shoot growth rates).

Low concentrations of H₂S trigger the ROL barrier formation

We found that low H₂S concentrations act as an environmental signal for the ROL barrier formation. This is the first observation where H₂S induced the formation of a ROL barrier in roots without a barrier exposed to concentration levels near EC₅₀ (10–20 μM), whereas a pioneer study showed that the presence of high H₂S concentrations, in combination with stagnant conditions, further enhanced the barrier strength (Armstrong & Armstrong, 2005). Concentrations near EC₅₀ are indeed found in some rice soils (Allam, 1971) and H₂S is therefore likely to act in concert with other signalling molecules for barrier formation under natural growth conditions. Consequently, we add another well-known by-product from anaerobic bacterial activity acting as an environmental signal for the barrier formation, for example reduced Fe (Mongon et al., 2014), low-molecular weight carboxylic acids (Armstrong & Armstrong, 2001; Colmer et al., 2019) and now H₂S. Interestingly, the H₂S-induced barrier tightness was similar to that induced in stagnant conditions (Fig. 4b), suggesting that regardless of the environmental signal, the net results of the histochemical modifications of the cell walls led to the same tightness to molecular O₂ even if the cell walls showed contrasting staining to lignin and suberin (Fig. 7).

We found that a weak barrier was present after 48 h (Fig. 4b) of exposure to H₂S or to stagnant conditions. This time response differs to that of a previous study where ROL was significantly reduced already after 6–12 h of exposure to stagnant conditions (Shiono et al., 2011), possibly because measurements were conducted at a different root position, that is closer to the root–shoot junction. On the other hand, high concentrations of H₂S (174 μM) enhanced barrier strength 30 mm behind the root tip within 24 h when H₂S was added into the stagnant medium.
(Armstrong & Armstrong, 2005). Both studies (present and Armstrong & Armstrong, 2005) indicate that the signalling effect of H2S is fast and similar to that of stagnant conditions (Shiono et al., 2011).

Gene regulation in ROL barrier formation

It has been suggested that phenylpropanoids, such as suberin or lignin, are the major components of the ROL barrier, although it is not clear which one has a more significant role (Kotula et al., 2009). Some genes were commonly upregulated under H2S and stagnant conditions, and different copies of suberin biosynthesis genes like KCS, GPAT, CYP86A4 were upregulated in both conditions (Table S7), and two GPAT genes (LOC_05g02340 and LOC_05g38350) have been shown to be specifically expressed in the exodermis (Nishiuchi et al., 2021). Previous studies have identified a number of genes related to suberin biosynthesis responding to stagnant conditions (Kulichikhin et al., 2014; Shiono et al., 2014). Compared to Shiono et al. (2014), only 15 genes overlapped with this study even under stagnant conditions. The little overlap is possibly due to the former study using the basal part of the root as compared with this study focusing on the apical region where the ROL barrier is being formed. By contrast, Kulichikhin et al. (2014) also focused on the apical region and showed significantly higher overlap with 459 genes commonly upregulated in the two studies. These findings suggest that the regulation during ROL barrier formation differs between the apical and basal parts of roots.

Moreover, several lignin biosynthesis-related genes were commonly upregulated in both H2S and stagnant conditions (Table 1), and six of these overlapped with Kulichikhin et al. (2014). LOC_05g0241680, LOC_05g0443760, and LOC_05g35290 all encode phenylalanine ammonia-lyase, LOC_09g04050 encodes cinnamoyl COA reductase, and LOC_05g10936848 encodes coniferaldehyde 5-hydroxylase. These enzymes are involved in phenylpropanoid biosynthesis and contribute to lignin biosynthesis (Yao et al., 2021). Additionally, LOC_09g362620 is a homolog gene of AtMYB43, which directly activates lignin biosynthesis genes (Geng et al., 2020). Altogether, these results suggest that the lignin biosynthesis pathway was activated in the outer part of root under H2S and stagnant conditions, indicating that lignin is also a major component of the ROL barrier in rice.

Histochemical staining revealed a clear pattern of lignin depositions during H2S exposure. The observed lignin staining with phloroglucinol and/or Maule reaction of roots growing in stagnant conditions (Fig. 7c,d) was similar to that of previous studies (e.g. Kotula et al., 2009; Ranathunge et al., 2011a). However, the pattern of H2S-exposed roots was strikingly different: lignin staining revealed that depositions occurred strongly at the sclerenchyma layer facing the exodermal cells, but lignin was also deposited between the exodermal cells as well (Fig. 7b,e). This could be related to the shape of exodermal cells that changed from a rectangular to a circular shape (Fig. 7b,e) allowing for more lignin depositions in the new intercellular spaces. Interestingly, this pattern was not observed in rice when exposed to other phytotoxins such as organic acids (Colmer et al., 2019) or with comparatively high concentrations of H2S in stagnant conditions (Armstrong & Armstrong, 2005).

Suberin was detected in all growth conditions, even in aerated controls. Similarly, low concentrations of organic acids induced a patchy layer of suberin (Colmer et al., 2019), whereas high concentrations of sulphides induced a more homogeneously developed suberin layer (Armstrong & Armstrong, 2005). This could be due to the higher sulphide concentration used, the fact that sulphide was added to roots growing in stagnant conditions, or different sampling times/positions behind the root tip. Regardless, staining for lignin was more extensive than suberin, correlating with the higher number of genes involved in lignin biosynthesis compared with suberin-related genes.

Conclusions

This study showed that the barrier to ROL effectively restricts radial H2S intrusion from the environment. Thereby, the mature zones of rice roots with a ROL barrier are well protected from the toxic effect of H2S. The EC50 for H2S is low and the toxic effects, once these occur, are severe as shown on root elongation. Moreover, H2S concentrations in the range of EC50 can also act as an environmental cue for the ROL barrier formation. The root ROL barrier can thus be seen as a jack of all trades as it not only conserves O2 in the root tissue by preventing ROL, but also restricts (1) radial water loss (Peralta Ogorek et al., 2021), (2) radial intrusion of reduced Fe (Jimenez et al., 2021), (3) intrusion of sodium (Ranathunge et al., 2011a), and (4) radial intrusion of H2S.
