Many protocols in quantum science and technology require initializing a system in a pure quantum state. In the context of the motional state of massive resonators, this enables studying fundamental physics at the elusive quantum–classical transition, and measuring force and acceleration with enhanced sensitivity. Laser cooling has been a method of choice to prepare mechanical resonators in the quantum ground state, one of the simplest pure states. However, to overcome the heating and decoherence by the thermal bath, this usually has to be combined with cryogenic cooling. Here, we laser-cool an ultracoherent, soft-clamped mechanical resonator close to the quantum ground state directly from room temperature. To this end, we implement the versatile membrane-in-the-middle setup with one fiber mirror and one phononic crystal mirror, which reaches a quantum cooperativity close to unity already at room temperature. We furthermore introduce a powerful combination of coherent and measurement-based quantum control techniques, which allows us to mitigate thermal intermodulation noise. The lowest occupancy we reach is 30 phonons, limited by measurement imprecision. Doing away with the necessity for cryogenic cooling should further facilitate the spread of optomechanical quantum technologies.

1. INTRODUCTION

Over the last decade, the relative simplicity and great versatility of membrane-in-the-middle (MIM) systems [1] have rendered them a highly popular choice for a variety of optomechanics experiments. To name just a few examples, they have been used for early demonstrations of optomechanical effects such as dynamical [2–5] and quantum backaction [6], optomechanically induced transparency [7], and Raman ratio thermometry [8,9], to implement coupling between mechanical and atomic degrees of freedom [10–13], to explore novel routes for enhanced sensitivity in gravitational wave detection [14–16], to study multimode [17–19] and topological physics [20], to manipulate the quantum state of light [21,22], and to realize electro–opto–mechanical transducers [23–26]. More recently, force sensing [27–29] and imaging [30] applications have received particular attention, due to the very low thermomechanical force noise [31–33], and the potential for very efficient optical detection of the sensor state [34,35]. Indeed, using a broadband correlation technique [36,37], this platform has even allowed continuous force measurements beyond the standard quantum limit (SQL) for the first time [38].

However, to reach the quantum regime, it has so far been necessary to cool the membrane to cryogenic temperatures [6,8–11,13,18,21,22,24–26,34,35,38]. For even greater flexibility and versatility, it would be desirable to be able to operate in the quantum regime already at room temperature. To date, few mechanical systems have even approached the quantum regime at room temperature, including optically levitated nanoparticles [39,40], select nano– [41–43] and micromechanical devices [44], as well as a set of macroscopic mirrors in a gravitational wave observatory [45]. Save for the latter, a broad range of applications have yet to be demonstrated with these platforms, in contrast to MIM systems. Our goal is therefore to implement a room-temperature MIM system in the quantum regime.

A key enabler towards this goal is a recently developed ultracohherent mechanical system, a “soft-clamped” membrane resonator [33], whose coherence at room temperature rivals those of standard membranes at cryogenic temperatures [6,18]. We also bring to bear several techniques to mitigate background thermal noises in the system, including a phononic mirror and a combination of sideband cooling and feedback cooling.
2. SOFT-CLAMPED MEMBRANE-IN-THE-MIDDLE SYSTEM

The membrane is placed inside a Fabry–Pérot optical resonator (Fig. 1), between a node and an anti-node of the standing optical wave in the cavity. We thereby implement the standard MIM dispersive optomechanical coupling [1] described by the Hamiltonian [46,47] $\hat{H}_{\text{om}} = \hbar g_0 a^\dagger a (b + b^\dagger)$. Here, $\hbar$ is the reduced Planck constant, $g_0$ the vacuum optomechanical coupling rate, and $a (a^\dagger)$ and $b (b^\dagger)$ the optical and mechanical annihilation (creation) operators, respectively. The membrane is 15 nm thick and patterned with a phononic crystal, which affords soft-clamping of an out-of-plane mechanical mode localized close to an intentionally introduced crystal defect [33]. In this work, we introduce a new design for both the crystal and the defect (which we refer to as the “Dandelion” design); see Fig. 1(b). Compared to the design used in our previous works [13,22,29,33–35,38], Dandelion-class defects exhibit significantly lower masses (up to a 30-fold reduction) when fabricated from identical substrates and targeting the same frequency and $Q$-factors. Additionally, the mechanical mode can be centered in an ~50% bigger bandgap, with typically only one extra mechanical mode in the bandgap (two total). However, these benefits come with a significant reduction in the size of the pad at the defect center, which can lead to complications with large cavity waists and/or optical alignment. As such, the optimal for any application is not necessarily the design with the smallest mass, highest $Q$-factor, or other figure of merit.

Specifically due to alignment tolerances, the particular design used in this work is a medium-size Dandelion with a central pad approximately 30 µm across, resulting in a mechanical mode with resonance frequency $\Omega_m / 2\pi = 1.3$ MHz and modal mass $m_{\text{eff}} \approx 200$ pg. This results in a relatively large amplitude of zero-point fluctuations, $s_{\text{zpf}} = \sqrt{\hbar / 2m_{\text{eff}}\Omega_m} = 5.7$ fm. Due to the soft-clamping effect, we achieve intrinsic damping rates $\Gamma_m / 2\pi \approx 9$ mHz, corresponding to quality factors as high as $Q_m = \Omega_m / \Gamma_m = 1.4 \times 10^8$ with these devices at room temperature, $T \approx 300$ K, where the occupation of the mechanical bath is as high as $n_{\text{th}} \approx k_B T / h \Omega_m \approx 5.1 \times 10^6$ ($k_B$ is the Boltzmann constant). This implies a thermomechanical decoherence rate of $\gamma = n_{\text{th}} \Gamma_m \approx 2 \pi \cdot 48$ kHz. In turn, this corresponds to $\Omega_m / \gamma \approx 27$ coherent oscillations, comparing favorably to similar experiments (four coherent oscillations [41]) and even levitated optomechanical systems (<15 coherent oscillations [39]).

The cavity consists of one curved and one flat mirror. We fabricate the curved mirror by laser-machining a concave indentation into the facet of a single-mode fiber, and subsequently coating it with a high-reflectivity coating [48,49]. To realize the flat mirror, a slightly different coating is deposited on a flat Pyrex glass wafer that has been bonded to a silicon “exoskeleton” support structure, whose role will be detailed in Section 4.B. The mirrors are set up to face each other with a distance of $L \approx 95$ µm. Details on the fabrication of the mirrors and the mechanical setup are provided in Supplement 1.

The mirror coatings are designed to provide a one-sided, high-finesse cavity at a wavelength of around 1550 nm. Independent measurements of the actually realized mirrors’ power transmissivities, $T_f$ and $T_c$ for the fiber and exoskeleton mirror, respectively, suggest an overcoupling of $\eta_c = T_f / (T_f + T_c) \approx 0.9$ for the cavity coupled through the fiber mirror. For the assembled cavity including a membrane, we measure the reflection signal through the (more transmissive) fiber mirror, as shown in Fig. 1(d). Using the model in [50] to fit the data, we obtain a FWHM cavity linewidth of $\kappa / 2\pi = 340$ MHz, corresponding to a finesse of $\mathcal{F} \approx 4400$. Note that the spatial filtering of the cavity leakage by the fiber mode leads to an asymmetric reflection signature (with two contributions of Lorentzian and dispersive shapes), the depth of which is not limited by the mode-matching efficiency $\varepsilon$ between the cavity and detected optical modes. See Supplement 1 for more details on the model.

The geometry of the indentation in the fiber mirror is approximately spherical with a 300 µm radius of curvature, leading to an approximately 10 µm waist of the cavity’s fundamental optical mode. This allows good transverse overlap ($\xi \sim 1$) of the optical and mechanical mode shapes, even for the small—and therefore low-mass—defect of the Dandelion design. Together with the short cavity length, this facilitates large vacuum optomechanical coupling, which can, for the optimal position of the membrane within the cavity standing wave, be approximated as

$$\xi_{0, \text{max}} \approx 2 \frac{\omega_m}{L} |r| s_{\text{zpf}} \frac{\xi}{\kappa},$$

where $\omega_m$ is the cavity resonance frequency, and $r$ is the membrane’s optical (field) reflectivity. Indeed, for the parameters of the system, we expect a coupling rate of $g_0 / 2\pi \approx 3.3$ kHz.
3. DYNAMICAL BACKACTION

Broadly speaking, to reach the quantum regime, it is necessary to achieve a quantum cooperativity \( C_q = 4g^2/(\kappa\gamma) \approx 1 \), where \( \kappa \) and \( \gamma \) are the optical and mechanical decoherence rates, respectively, and \( g = g_0\sqrt{n_{eq}} \) is the field-enhanced coupling rate with the intracavity photon number \( n_{eq} \). In a first set of experiments, we infer the obtained coupling by analyzing dynamical backaction [2–5] on the mechanical mode.

To this end, we couple a low-noise laser (NKT Photonics Koheras Basik E15) of wavelength \( \lambda = 1542 \text{ nm} \) to the cavity. We derive two beams from this laser: a “probe” beam to lock the cavity on resonance with one of its fundamental modes using a Pound–Drever–Hall locking scheme, and to read out the mechanical motion via a homodyne interferometer. A second, “cooling” beam is offset by \(-80 \text{ MHz}\) via a fiber-based acousto-optic modulator, and its polarization is made orthogonal to that of the probe. These two facts help minimize the unwanted effect of the cooling beam on the measurement record. Figure 2(a) shows the schematic of the experimental setup, an extended discussion of which is presented in Supplement 1.

As we increase the cooling beam power, we observe the evolution of the mechanical noise spectrum through the probe homodyne detector. We extract the mechanical frequency shift \( \delta \Omega_m \) resulting from the optical spring effect, as a function of the cooling beam power (cf. Fig. 2(b)). The standard model for the mechanical frequency shift by an optical spring [46],

\[
\delta \Omega_m = g_c^2 \left( \frac{\Delta_c - \Omega_m}{\kappa^2/4 + (\Delta_c - \Omega_m)^2} + \frac{\Delta_c + \Omega_m}{\kappa^2/4 + (\Delta_c + \Omega_m)^2} \right),
\]

supplied with the independently known \( \Omega_m, \kappa, \) and detuning \( \Delta_c \), allows us to extract the field-enhanced coupling rate \( g_c \) as a function of measured power. The index “c” here refers to the cooling beam. For a given power, we can estimate the intracavity photon number by estimating the incoupling efficiency of light. In this manner, we infer an experimental value for the vacuum optomechanical coupling rate of \( g_0/2\pi = 2.3 \text{ kHz} \), in good agreement with the theoretical value, assuming slightly sub-optimal longitudinal and transverse positioning of the membrane.

We also compare the observed broadening of the mechanical linewidth with the expected damping due to dynamical backaction of the cooling beam [46],

\[
\Gamma_m^c = g_c^2 \left( \frac{\kappa}{\kappa^2/4 + (\Delta_c + \Omega_m)^2} - \frac{\kappa}{\kappa^2/4 + (\Delta_c - \Omega_m)^2} \right),
\]

for all of the inferred couplings \( g_c \), and find good agreement. Specifically, in Fig. 2(c), we show the total damping rate \( \Gamma_m^c = \Gamma_m + \Gamma_m^p + \Gamma_m^\text{tot} \), with \( \Gamma_m^p \) the contribution from optical damping by the (very slightly red-detuned) probe beam. To allow for this probe-induced damping, the dashed line is a fit with the vertical offset as the only free parameter, but is otherwise fully constrained by independently known parameters (\( \Omega_m, \kappa, \) and \( \Delta_c \)) and the fit of the optical spring. The fit to the linewidths yields \( \Gamma_m^p/2\pi = 4.6 \text{ Hz} \), corresponding to a probe detuning \( \Delta_p/2\pi \approx -2 \text{ MHz} \). The zero-power linewidth is likely overestimated due to inhomogeneous broadening caused by a fluctuation in coupled laser power.

Finally, we confirm that we can increase the probe power further, into a regime where \( C_q \approx 1 \) would be expected, without the onset of optomechanical (or other) instabilities.

4. LASER COOLING CLOSE TO THE QUANTUM GROUND STATE

A. Theoretical Cooling Limits

Next we aim at preparing the mechanical system in a pure quantum state—specifically, the quantum ground state. That is, starting from the equilibrium value \( \bar{n}_h = 5.1 \cdot 10^4 \), we want to reduce the residual mechanical occupation \( \bar{n} = \langle b^\dagger b \rangle \rightarrow 0 \). Laser sideband cooling has been used with great success to cool mechanical oscillators, including MIM systems [2–5,18,38]. Adapting the theory of sideband cooling yields the final occupation [46]

\[
\bar{n} = \frac{\bar{n}_h \Gamma_m (1 + C_q) + \bar{n}_c \Gamma_m^c}{\Gamma_m^{\text{tot}}},
\]

where \( \Gamma_m^{\text{tot}} \) in the denominator allows for a small probe detuning, the numerator accounts for the probe’s quantum backaction (with \( C_q \approx 1 \) the probe’s quantum cooperativity), and
\[ \bar{n}_{m} = \frac{(\Omega_m + \Delta_r)^2 + (\kappa/2)^2}{4\Delta_r \Omega_m} \] (5)

is the minimum occupancy that can be reached in the limit of strong cooling \( \Gamma_m \gg \bar{n}_{g} \Gamma_m (1 + C_q) \), due to quantum backaction of the cooling beam. In the unresolved-bandside regime with \( \kappa \gg \Omega_m \), in which we work here, \( \bar{n}_{m} \approx \kappa/4\Omega_m \) for optimal detuning \( \Delta_r \), corresponding to about 65 phonons for the parameters of our system. We note that Eq. (4) should, in principle, also contain classical backaction, i.e., photothermal heating and intensity noise heating, which would manifest as an effective thermal bath occupation that increases with optical power. The analysis of the mechanical area as a function of optical power presented in Supplement 1 shows, however, that this effect is negligible.

Given that sidetband cooling to the ground state is prohibited by quantum backaction, we additionally expect to use measurement-based quantum control techniques [34, 35, 40, 47, 51–54] to reach it. In these approaches, one tracks the mechanical position \( x(t) = x_{qr}(b(t) + b^\dagger(t)) \) through the optical signal, in our case the output \( y(t) \) of the homodyne interferometer detecting the probe light. A sufficiently precise measurement record allows tracking the state of the oscillator, and preparing it in a highly pure conditional quantum state [35]. Alternatively, one can derive a feedback force \( F_g(t) = h b_g(t) * y(t) \) from the measured displacement, where \( h b_g(t) \) is a filter kernel, and * denotes a convolution. Applying this force to the mechanical resonator allows preparing it in its ground state unconditionally [34].

Importantly, the measured signal \( y(t) = x(t) + x_{\text{imp}}(t) \) contains, apart from the desired \( x(t) \), also the imprecision \( x_{\text{imp}}(t) \), a noise background inevitable in the kind of interferometric measurement discussed here [55]. For optimal gain in the feedback loop, the minimum occupation that can be reached can be written approximately as (see Supplement 1)

\[ \bar{n}_{\text{th}} \approx \left( \sqrt{\frac{\bar{S}_{\text{FF}}}{4\hbar^2}} - \frac{1}{2} \right)^2 \] (6)

Here, \( \bar{S}_{\text{FF}} \) is the (symmetrized, single-sided) spectral density of force fluctuations driving the mechanical resonator, whereas \( S_{\text{xx}} \) is the spectral density of \( x_{\text{imp}} \). We assume these spectral densities are constant in the relevant range around the mechanical frequency \( \Omega_m \) and have dropped the frequency argument for brevity. The total force fluctuations \( \bar{S}_{\text{FF}} = \bar{S}_{\text{FF}} + \bar{S}_{\text{FF}} \) contain both the thermal Langevin force noise \( \bar{S}_{\text{FF}} = 4 m_{ch} \Gamma_n k_B T \), as well as the radiation pressure fluctuations of the intracavity light field(s) \( \bar{S}_{\text{FF}} \). If the latter are given only by quantum fluctuations, we have \( \bar{S}_{\text{FF}} = C_q \bar{S}_{\text{FF}} \).

The imprecision, in turn, must at least contain the quantum (shot) noise in the optical detector. This ensures that the Heisenberg measurement-disturbance uncertainty relation \( \bar{S}_{\text{FF}} \bar{S}_{\text{FF}} \geq \hbar^2 \) is always respected [46, 47, 55]. For imperfect detection efficiency \( \eta_{\text{det}} \), the imprecision as referenced to equivalent mechanical displacement grows, and \( \bar{S}_{\text{FF}} \bar{S}_{\text{xx}} \approx \hbar^2/\eta_{\text{det}} \) if both radiation pressure and imprecision noise are limited by quantum fluctuations otherwise [56]. We can additionally take into account the classical contribution to the imprecision noise \( \bar{S}_{\text{imp}} \), for example, due to fluctuations of the cavity mirrors, which produce cavity length changes unrelated to (but indistinguishable from) membrane motion. We then have \( \bar{S}_{\text{xx}} = \bar{S}_{\text{xx}} + \bar{S}_{\text{imp}} \) and \( \bar{S}_{\text{imp}} \approx \bar{S}_{\text{imp}} + \bar{S}_{\text{imp}} \)

Evidently, for quantum-limited \( \bar{S}_{\text{xx}} \rightarrow 0 \), strong \( C_q \gg 1 \), and efficient \( \eta_{\text{det}} \rightarrow 1 \) measurement, the ground state can be reached. This is demonstrated in [34] for a MIM system and [40] for a levitated nanoparticle.

**B. Imprecision Noise Analysis**

Key challenges when moving from cryogenic to room temperature operation include that not only the quantum cooperativity \( C_q \propto 1/\bar{n}_{\text{th}} \) but also the classical imprecision contribution \( \bar{S}_{\text{xx}} \) to the quantum imprecision noise heating, which would manifest as an effective thermal bath occupation that increases with optical power. The analysis of the mechanical area as a function of optical power presented in Supplement 1 shows, however, that this effect is negligible.

The first is laser frequency (or phase) noise. The spectral density of laser frequency fluctuations \( \bar{S}_{\text{xx}} \) close to \( \Omega_m \) can be rescaled to effective displacement using the frequency pull parameter \( d_{\text{xx}} = g_0/\bar{S}_{\text{xx}} \) [cf. Eq. (1)]. If the corresponding imprecision \( \bar{S}_{\text{imp}} \) dominates the quantum imprecision, this leads to a minimum occupation of the order of \( \bar{n}_{\text{th}} \approx \bar{n}_{\text{th}}/g_0/\bar{S}_{\text{xx}} \approx 1 \) for \( C_q \approx 1 \). Interestingly, a similar limit has been derived and observed for laser sidetband cooling [57–59].

In our experiment, the frequency noise of the employed laser is specified as \( \bar{S}_{\text{xx}} \approx (2\pi \cdot 1 \text{ Hz})^2/\text{Hz} \), leading to a negligible contribution as \( \bar{n}_{\text{th}} \approx \bar{n}_{\text{th}}/g_0/\bar{S}_{\text{xx}} \approx 1 \), much smaller than the quantum imprecision term \( 1/\eta_{\text{det}} C_q \) (see below).

To analyze the second potential contribution, we need to note that the transduction of the cavity frequency fluctuations into the optical field is inherently nonlinear. As shown in [61], these nonlinearly transduced frequency fluctuations result in a broadband “thermal intermodulation noise” (TIN) that can dominate the noise in photodetection when the linearly transduced fluctuations are small, e.g., when detecting the intensity of a resonant beam (as in [61]). Conversely, for a homodyne measurement of a resonant beam’s phase, employed in our work, the linear contribution is maximal. Moreover, the leading nonlinear term is not quadratic, but cubic in small fluctuations, which leads to a more favorable scaling of different contributions to TIN (see Supplement 1 for more details).

Finally, because our MIM cavity is deep in the unresolved-bandside regime, the cooling beam provides sidetband cooling of a wide range of mechanical modes, which should alleviate the effect of TIN even further [62], such that we expect not to be limited by it. While TIN-related intensity noise can still be present in the system, it neither appears in the cavity scans (Fig. 1(d)) nor does it manifest as excess heating, as discussed before.

A third relevant source of classical imprecision noise is thermal fluctuations in the cavity mirrors. This phenomenon has been studied extremely carefully in the context of the large mirrors employed in gravitational wave observatories, and a number of possible mechanisms have been identified [63]. More compact cavities with millimeter-scale mirrors are typically dominated by the thermal fluctuations of the mirror substrate, displacing the boundary off which the light is reflected. Since the mirror substrates in general support a discrete set of mechanical resonance...
modes, the spectra of these fluctuations are expected to consist of a series of relatively sharp peaks, depending on the Q-factor of the mirror modes. Such spectra have been systematically studied for some two decades [64–66], and indeed even used as mechanical modes in early optomechanics experiments [64]. They have also constituted a limiting factor of MIM experiments, where they can mask quantum effects in the spectral regions where the peaks appear [18,38,67]. At room temperature, peak displacement spectral densities at the level of $(1-10\,\text{am})^2/\text{Hz}$ have been measured for commonly employed mirror geometries [64–66].

The purpose of our flat mirror’s “exoskeleton” [shown in Fig. 3(a)] is to reduce the impact of this noise. Indeed, this silicon substrate is structured with a phononic crystal similar to the one employed as membrane support in earlier work [68,69]. It is modified in such a way that if bonded to the Pyrex wafer that carries the mirror reflective coating, the joint structure exhibits an acoustic bandgap in the MHz frequency regime. We have verified the existence of the bandgap by measuring the out-of-plane motion of the mirror surface in response to a swept excitation with a piezoelectric transducer [Fig. 3(b)]. Within the bandgap, we therefore expect no substrate thermal noise peaks to appear at a relevant level.

Informed by earlier studies of guided acoustic-wave Brillouin scattering in single-mode fiber [70], we would expect the acoustic resonances of the fiber mirror to exhibit a sparse spectrum and in particular remain confined to high frequencies $\gtrsim 10\,\text{MHz}$. A dedicated study [71] of a fiber cavity has revealed, however, that, e.g., fiber bending modes can occur already in the MHz regime, and more importantly, also the existence of a broadband noise at the level of about $(20\,\text{am})^2/\text{Hz}$ in the MHz frequency region.

We have independently analyzed the background noise in our composite exoskeleton/fiber-mirror cavity, with a dedicated measurement of its apparent displacement noise with the membrane removed. The result is shown in Fig. 3(c). Not only does it display peaks already above 2 MHz, but it does indeed also show broadband noise, which reaches the level of $\sim (10\,\text{am})^2/\text{Hz}$ at 1 MHz, well compatible with earlier measurements [71] (note that we use only one fiber mirror). We interpret the absence of any signature of the exoskeleton’s bandgap in this joint noise spectrum to be a consequence of the fact that the latter is dominated by broadband noise of the fiber mirror. Whereas this noise is certainly sub-ideal, we can tolerate the associated level of classical imprecision (with $\chi_m \approx 0.5$) in the current experiments, since the quantum noise contribution is much larger (see below).

Quantum noise in the detection is the last contribution to consider. For a resonant probe in the unresolved-sideband regime, the equivalent displacement noise power spectral density is given by $\tilde{S}_\text{det} = \hbar^2/\eta_{\text{det}}C_m^2$ [42]. Here, the overall detection efficiency is determined by the product $\eta_{\text{det}} = \varepsilon \cdot \eta_c \cdot |\beta|^2 \cdot P_{\text{QE}}$, with the efficiency $\varepsilon \cdot \eta_c$ for coupling cavity photons into the guided fiber mode, fiber losses $|\beta|$, homodyne fringe visibility $V$, and the photodetectors’ quantum efficiency $P_{\text{QE}}$. We achieve $\eta_{\text{det}} \approx 1.2\%$, dominated by a relatively low cavity mode matching $\varepsilon \approx 4\%$; see Supplement 1 for details. We determine the quantum cooperativity $C_m = 4g^2/K\gamma$ of the probe from the measured power ratio of the two beams, their known detunings, and the cooling beam’s coupling rate $g_e$ as determined by the dynamical backaction measurements described in Section 3.

Our laser does not provide enough optical power to reach unity cooperativity with the probe, and simultaneously feed the cooling beam and local oscillator with sufficient power. We therefore operate with a relatively modest probe power, corresponding to $C_m = 0.1$. We then have enough optical power available for the local oscillator to overwhelm the detectors’ electronic noise with shot noise. Whereas higher quantum cooperativity would certainly be desirable, the achieved value constitutes a significant advancement over many tabletop room-temperature experiments, reaching $C_m \approx 10^{-5}$ [43], $C_m < 10^{-4}$ [5], $C_m \approx 4 \cdot 10^{-3}$ [41], and $C_m \approx 5 \cdot 10^{-3}$ [42], and is on par with that in [44]. With this available probe power, the expected quantum imprecision of $\Delta_\text{tot} \approx (210\,\text{am})^2/\text{Hz}$ is still well above the mirror noise.

C. Cooling Results

To cool the membrane mode close to its motional ground state, we employ the setup shown in Fig. 2(a), and described already in Section 3. Additional details can be found in Supplement 1. Cooling proceeds via the combined effect of laser sideband and feedback cooling. That is, the cooling beam is detuned by $\Delta_c/2\pi \approx -80\,\text{MHz}$ from the cavity resonance, and its dynamical backaction damps the mechanical motion. The corresponding “anchor” spectrum of mechanical fluctuations is recorded by homodyne detection of the second, probe beam. The broadened mechanical resonance width $\Gamma_{\text{det}}/2\pi \approx 52\,\text{Hz}$ can be straightforwardly extracted from the homodyne spectrum via a Lorentzian fit. Together with independently determined optical ($\Delta_c$, $\kappa$) and mechanical ($\Omega_m$, $\Gamma_m$) parameters, we can estimate the resulting occupation $\tilde{n}$ of the mode after sideband cooling from Eqs. (4) and (5). Here, the bare mechanical damping $\Gamma_m$ is obtained from ringdown measurements in a different setup and corrected for slightly different pressure; see Supplement 1 for details. The calculated sideband-cooled mode occupation $\tilde{n} \approx 1070$ quanta is then used to calibrate the homodyne spectrum, which is originally recorded in electrical (voltage) units. That is, the measured homodyne spectrum $\tilde{S}_\text{dd} = \tilde{S}_\text{tot} + \tilde{S}_\text{imp}$ is calibrated in displacement units so that

\[\tilde{n} = \int_0^\infty \frac{\tilde{S}_\text{tot} - \tilde{S}_\text{det}}{2\pi^2} \frac{d\Omega}{\Delta_\text{tot}} \frac{1}{2}.\]

holds, whereby $\tilde{S}_\text{tot} = |\chi_m^{\text{tot}}(\Omega)|^2 S_{\text{tot}}^{\text{tot}}$ and $\chi_m^{\text{tot}}(\Omega)$ is the Lorentzian mechanical susceptibility modified by dynamical backaction.

We now turn on the feedback cooling of the membrane mode. To this end, the homodyne signal $y(t)$ is filtered and amplified, and subsequently used to modulate the radiation-pressure force $F_R(t) = h_{\text{fb}}(t) \cdot y(t)$ exerted by the cooling beam via the acousto-optical modulator [Fig. 2(a)]. In the frequency domain, the filter’s transfer function is of the form $h_{\text{fb}}(\Omega) = h_{\text{main}}(\Omega) + h_{\text{aux}}(\Omega)$, with

\[h_{\text{main}}(\Omega) = G_{\text{FB}} e^{i(\Omega_{\text{fb}} - \phi_{\text{fb}})} \left[ \frac{\Gamma_{\text{fb}}}{\Omega_{\text{fb}}^2 - (\Omega - i\Gamma_{\text{fb}})^2} \right]^{2} \times \frac{1}{\Delta_\text{tot}^2 - \Omega^2 - i\Gamma_{\text{FB}}\Omega}.\]

Here, $G_{\text{FB}}$ is the overall feedback gain, the main filter central frequency is $\Omega_{\text{fb}}/2\pi = 1.34\,\text{MHz}$, and the bandwidth $\Gamma_{\text{FB}}/2\pi = 77.86\,\text{kHz}$. The total delay is measured to be $\tau_{\text{fb}} \approx 300\,\text{ns}$, and the phase $\phi_{\text{fb}}$ is adjusted so as to give arg($h_{\text{fb}}(\Omega_{\text{fb}}^{\text{tot}})) \approx \pi/2$ (where $\Omega_{\text{fb}}^{\text{tot}} = \Omega_m + \delta \Omega_m + \delta \Omega_m^p$, and $\delta \Omega_m^p$ is the optical spring from
of quanta, \( \bar{\xi} \), \( \bar{\eta} \). Feedback gain. 

assumption that this conversion is not affected by changes in the 

window around 1.5 MHz. The sharp peak within this window is an externally applied calibration tone. The light gray trace corresponds to detection noise. 

Figure 4 shows the homodyne spectra measured with the feed-

back loop closed, and plotted normalized to the peak spectral 
spectrum in the absence of feedback (\( S_{xx}^{\text{tot}} \)). 

Figure 4(b) shows the frequency region of the exoskeleton bandgap.

whereas the measured (in-loop) homodyne spectra are modified as 

\[ S_{xx}(\Omega) = \left| \chi_f(\Omega) \right|^2 \left( S_{xx}^{\text{imp}} + |h_f(\Omega)|^2 \right) \bar{S}_{xx}^{\text{imp}} \] 

\[ S_{xx}(\Omega) \approx \frac{\bar{\eta}_c}{1 - \bar{\eta}_c h_f(\Omega)} \] 

Moreover, the measurement (imprecision) noise is now fed 
back as a force, so that 

\[ \bar{S}_{xx}(\Omega) = |\chi_f(\Omega)|^2 \left( S_{xx}^{\text{imp}} + |h_f(\Omega)|^2 \right) \bar{S}_{xx}^{\text{imp}} \] 

whilst the measured (in-loop) homodyne spectra are modiﬁed as 

\[ \bar{S}_{xx}^{\text{imp}}(\Omega) \approx \frac{\bar{\eta}_c}{1 - \bar{\eta}_c h_f(\Omega)} \] 

Figure 4 also shows that the imprecision noise is propor-
tional to the feedback gain, \( G_f \).

5. DISCUSSION

Research Article

Vol. 10, No. 3 / March 2023 / Optica

Regarding improvements to the experiment’s performance, first 
and foremost, better alignment should help remedy the most 
signiﬁcant optical losses due to poor mode matching between 
the cavity mode and the single-mode fiber. This should be possible 
by using a more precise alignment stage that positions the ﬁber 
within the cavity mode and the single-mode ﬁber. This should be possible 
by using a more precise alignment stage that positions the ﬁber 
within the cavity mode and the single-mode ﬁber. This should be possible 
by using a more precise alignment stage that positions the ﬁber
of the potential contributions to classical imprecision, which stem from imperfect control of the cooling beam polarization (by allowing for a larger LO power) and from TIN (by enabling stronger sideband cooling) in the absence of other imprecision noise. Realistic further improvements to an overall detection efficiency of \(\eta_{\text{det}} = 50\%\) then enable \(\bar{n} < 1\) even in the presence of fiber mirror noise, according to Eq. (7). To reach \(\bar{n} < 0.5\), the mirror noise could be suppressed by a factor of 10. This might be accomplished by replacing the fiber mirror with a second exoskeleton mirror, featuring a concave indentation made by laser ablation [72] or by solvent vapor reflow and reactive ion etching [73].

In comparison with other experiments performing feedback cooling of room-temperature devices, our achieved occupancy is orders of magnitude below what has been demonstrated with most suspended mechanical systems [53,74,75] and on par with state-of-the-art nanodevices (\(\bar{n} = 27\)) [41], as well as the test masses in advanced LIGO (\(\bar{n} = 11\)) [45]. Lower occupancies (\(\bar{n} < 1\)) have recently been achieved with nanoparticles held in optical traps [39,40], which are some five orders of magnitude lighter than the resonators studied here. We see a great potential of the membrane platform for room-temperature quantum experiments, due to its relative simplicity and great versatility. In addition to the many possibilities arising from a quantum-enabled optomechanical interface (see Introduction), membrane resonators can be functionalized to couple to charge [23,24] or spin [27,28], and can be decorated with samples such as viruses or metal nanoparticles [30]. This opens many application prospects that may benefit from initializing the mechanical system in a low-entropy state, e.g., by allowing to discern small displacements in phase space. A particularly interesting prospect would also be to implement a compact, wavelength-agnostic, room-temperature source of broadband ponderomotive squeezing [76].
