Abstract

Winning lottery tickets refer to sparse subgraphs of deep neural networks which have classification accuracy close to the original dense networks. Resilient connectivity properties of such sparse networks play an important role in their performance. The attempt is to identify a sparse and yet well-connected network to guarantee unhindered information flow. Connectivity in a graph is best characterized by its spectral expansion property. Ramanujan graphs are robust expanders which lead to sparse but highly-connected networks, and thus aid in studying the winning tickets. A feedforward neural network consists of a sequence of bipartite graphs representing its layers. We analyze the Ramanujan graph property of such bipartite layers in terms of their spectral characteristics using the Cheeger’s inequality for irregular graphs. It is empirically observed that the winning ticket networks preserve the Ramanujan graph property and achieve a high accuracy even when the layers are sparse. Accuracy and robustness to noise start declining as many of the layers lose the property. Next we find a robust winning lottery ticket by pruning individual layers while retaining their respective Ramanujan graph property. This strategy is observed to improve the performance of existing network pruning algorithms.

1. Introduction

Neural Network (NN) and its recent advancements have made a significant contribution to solve various machine learning applications. The power of an over-parameterized NN lies in its capability to learn simple patterns and memorize the noise in the data (Neyshabur et al., 2018). However, the training of such networks requires enormous computational resources, and often the deployment onto low-resource environments such as mobile devices, or embedded systems becomes difficult. Recent trend in research to reduce training time of deep neural networks has shifted towards pre-training following the introduction of a remarkable contribution, named the Lottery Ticket Hypothesis (LTH), which hypothesize the existence of a highly sparse subnetwork and weight initialization to reduce the training resources as well (Frankle & Carbin, 2019). It uses a simple iterative, magnitude-based pruning algorithm, and empirically shows that even after removing approximately 90% of the weights, the subnetwork can preserve the original generalization error. In the subsequent studies, the focus goes on finding this lottery ticket for more competitive tasks by pruning with weight rewinding (Frankle et al., 2019), fine tuning the learning rates (Renda et al., 2020), more efficient training (You et al., 2019; Brix et al., 2020; Girish et al., 2021).

Various analysis for explaining the LTH have been attempted in the past. Researchers (Evci et al., 2020b) explain empirically why the LTH works through gradient flow at different stages of the training. Despite previous attempts to explain why the Lottery Ticket Hypothesis works, the underlying phenomenon associated with the hypothesis still remains ill-understood. All of these studies related to LTH identify that a sparse sub-network can be trained instead of a complete network and the network needs to be connected from input to output layers. However, none of them try to explain the LTH and the properties of the pruned network through the lens of spectral graph theory. The network connectivity can be described from the graph expansion point of view, where any subset of vertices of size less than or equal to half of the number of vertices in a graph, is adjacent to at least a fraction of the number of vertices in that set; for details, see (Lubotzky, 2010). Graphs satisfying this property are known as expander graphs. The Ramanujan Graph is a special graph in a bounded degree expander family, where the eigenbound is maximal (Nilli, 1991). This leads to a maximum possible sparsity of a network while preserving the connectivity.

In this paper, we initiate a study to observe the characteristics of a pruned sub-network from the spectral properties
of its adjacency matrix, which has not been reported previously. We represent a feed-forward neural network as a series of connected bipartite graphs. Both weighted and unweighted bi-adjacency matrices are considered. The Ramanujan graph properties of each of the bipartite layers are studied. We use the results of (Hoory, 2005) on the bound of spectral gap for the weight matrix of a pruned network. It is empirically observed that existence of winning tickets in a pruned network is dependent on the Ramanujan graph properties of the bipartite layers. As network sparsity increases with more aggressive pruning, we obtain regions where test set accuracy does not decrease much and the bipartite layers satisfy Ramanujan graph property. Subsequently we obtain regions where the Ramanujan graph properties are lost for all the layers and test accuracy decreases sharply. Also, we observe that the impact of noise in the data, on test set accuracy is more adverse when some of the layers lose their Ramanujan graph properties. Experimental results are presented for the Lenet architecture on the MNIST dataset and the Conv4 architecture on the CIFAR10 dataset. Results for other popular feed-forward network are presented in the Appendix.

We suggest that preservation of Ramanujan graph properties may benefit existing network pruning algorithms. We propose a modified pruning algorithm that uses the spectral bounds. The algorithm identifies network layers that may still be pruned further, while avoiding pruning in layers that have already lost their Ramanujan graph property. Neural network weight score functions suggested by various pruning algorithms are used to represent the bipartite layers as weighted graphs. Spectral bounds for these graphs are used to verify the Ramanujan property. For a number of popular pruning algorithms, we experimentally demonstrate significant improvement in accuracy for sparse networks by using these connectivity criteria. **Contributions:** The contributions of the paper are the following:

- We propose a methodology for analyzing winning lottery tickets with respect to their spectral properties.
- We empirically observe that winning lottery tickets often satisfy layerwise bipartite Ramanujan graph property representing a sparse but resiliently connected global network. The property is checked using spectral bounds that generalize to irregular networks. We also notice better noise robustness when all the layers of the pruned sparse networks preserve this property.
- Based on the above property we propose a modified iterative network pruning algorithm that attempts to preserve Ramanujan graph property for all the layers even at low network densities. It identifies layers that are still amenable to pruning while avoiding further pruning in layers that have lost their Ramanujan graph property.

Section 2 and 3 brief the lottery ticket hypothesis and the expander graphs, respectively. Section 4 and 5 discuss the proposed approach and the results, respectively. Section 6 reviews related literature and Section 7 concludes the work.

## 2. The Lottery Ticket Hypothesis and Network Pruning

The lottery ticket hypothesis states that a randomly initialized, dense neural network contains a subnetwork which when trained independently using the same initialization achieves a test accuracy close to the original network after training for less or at most the same number of iterations (Frankle & Carbin, 2019). These subnetworks, denoted as ‘winning tickets’, can be uncovered by network pruning algorithms. Weight pruning is one such simple strategy. Let the original dense network be represented as the function \( \mathcal{N}(x; \theta) \), where \( x \) is the input and \( \theta \) are the weights. The weights have an initialization of \( \theta_0 \). Weight pruning generates a mask \( m \in \{0, 1\}^{\theta} \) such that the pruned network can be represented by \( \mathcal{N}(x; m \odot \theta) \) with initialization \( m \odot \theta_0 \).

Pruning algorithms that are used to obtain the winning tickets can be either one-shot or iterative. In one-shot pruning the original network is trained to convergence, then \( p\% \) of weights are pruned and the surviving weights are re-initialized to their values in \( \theta_0 \) followed retraining/fine tuning the subnetwork. Here, the network training and pruning are not simultaneously performed and pruning occurs only after convergence is reached. Iterative pruning repeats one-shot pruning over several iteration. This often leads to higher pruning percentage while retaining test set accuracy. However, iterative pruning is more time consuming than one-shot pruning. After pruning the surviving weights may alternately be initialized to their values in \( \theta_i \), \( i \) denoting a small iteration number, rather than their initial values in \( \theta_0 \). This process is effective for large networks. We adopt this in our study. Various scoring functions are used to prioritize the weights for pruning. They may be based on weight magnitudes, gradient, information flow (Blalock et al., 2020; Hoeffer et al., 2021) or saliency (Tanaka et al., 2020). Magnitude pruning provides a simple method for obtaining the pruning mask by retaining the top \( p\% \) weights \( w_i \in \theta \) that have the highest values of \( |w_i| \). The role of the weights in local computation in the network layers is not considered. A higher pruning efficiency may be achieved by algorithms that account for connectivity structures in the individual layers. In the next section we describe graph parameters of the network that determine such connectivity.

## 3. Expanders and Ramanujan Graphs

Expanders are highly connected, and yet sparse graphs. In this work, we shall be considering finite, connected, undi-
The fact that in a bounded degree expander family, the eigenvalue bound in Ramanujan graphs is maximal can be deduced from the following result due to Alon, see (Nilli, 1991), $t(\mathcal{G}) \geq 2\sqrt{r-1} - \frac{2\sqrt{r-1}}{\lceil m/2 \rceil} - 1$ where $m$ denotes the diameter of the graph. As $m \to +\infty$ and $r$ is bounded, we obtain the result (this also follows from the Alon-Boppana theorem).

For our applications, we shall encounter not necessarily regular graphs, thus we need a notion of irregular version of Ramanujan graphs. The two ways we shall exploit Definition 3.3 for irregular graphs will be to: (i) Use the average degree $d_{\text{avg}}$ in place of the regularity; (ii) For weighted graphs, use $t_1$, the largest eigenvalue of the adjacency matrix. Note that a motivation for considering the above bounds comes from the following generalisation of the definition of Ramanujan graphs to irregular graphs. For a finite, connected graph $\mathcal{G}$ (not necessarily regular) consider its universal cover $\mathcal{G}$, for details see (Hoory et al., 2006, sec. 6). A Ramanujan graph is a graph satisfying $t(\mathcal{G}) \leq \rho(\mathcal{G})$ where $\rho(\mathcal{G})$ denotes the spectral radius of $\mathcal{G}$. See also Marcus–Spielman–Srivastava (Marcus et al., 2015, sec. 2.3). A result of Hoory, see (Hoory, 2005) implies that $2\sqrt{d_{\text{avg}} - 1} \leq \rho(\mathcal{G})$. Thus, it makes sense to consider $t(\mathcal{G}) \leq 2\sqrt{d_{\text{avg}} - 1} \leq \rho(\mathcal{G})$. The above consideration also result in extremal families, (Hoory, 2005). Further, for irregular bipartite graphs, with minimal degree at least two and an average degree $d_{\text{avgL}}$ on the left and $d_{\text{avgR}}$ on the right, we can further consider the sharper estimate $t(\mathcal{G}) \leq \sqrt{d_{\text{avgL}} - 1} + \sqrt{d_{\text{avgR}} - 1} \leq \rho(\mathcal{G})$ see (Hoory, 2005).

Upto now, we had only discussed about unweighted graphs. A weighted graph is a graph with a weight function $w : E \to \mathbb{R}_{\geq 0}$ attached on the edges. It can be looked upon as a generalisation of unweighted graphs, in the sense that in the unweighted case, the function $w$ takes values in the set $\{0, 1\}$. In the case of weighted one, we shall use the absolute values of the weight functions according to the architecture for the corresponding dataset. It also means that in the case of weighted graphs, we need to modify the definition of the edge set of the graph to incorporate multiple (as well as fractional) edges. The theory of characterisation of weighted Ramanujan graphs is not well developed. However, characterisation of weighted expanders (with positive weights) exist, due to the Cheeger inequality for such graphs, see (Chung, 1996, sec. 5) and we use the largest eigenvalue of the adjacency matrix in place of the regularity. In the case of regular graphs, it coincides with the notion of Ramanujan graphs and even in the general case, by Cheeger inequality, it ensures a large expansion which in turn supports free flow of information. It forms the theoretical basis of our work.

4. Ramanujan Graph Characterization of Neural Networks

We can represent any neural network using graphs (possibly weighted, depending on the context) and in this article, we
will be dealing with a sequence of finite, bipartite graphs. This is because if \( N \) denotes a neural network having \( l \) layers \( N_1, N_2, \ldots, N_l \), respectively, then each \( N_i \) \((i = 1, 2, \ldots, l)\) is a complete bipartite graph to start with. A pruned subnetwork results in edge sparsification of the underlying graphs. For that purpose, we need to approximate complete, bipartite graphs by sparse, proper subgraphs. The motivation to study pruning based on expander characteristics stems from the fact that complete graphs can be approximated using expanders, see (Spielman, 2018). The notion of Ramanujan graphs allow us to quantify the pruning limit, and we empirically justify our technique.

![Figure 1](image1)

**Figure 1.** Examples of small feed-forward networks having same sparsity but different connectivity properties; (a) disconnected network, (b) partially connected (c) strongly connected. When all of them are scaled to larger networks, (c) has large spectral gap compared to (a) and (b) signifying a high rate of expansion.

In Figure 1, we present examples of three small feed-forward networks with a single hidden layer and four neurons in each layer. The networks consist of two bipartite graphs corresponding to the input-hidden and hidden-output layers. The sparsity of all the three networks, as measured by the number of edges present, are the same. However, in the first network none of the layer-wise bipartite graphs satisfy the expander property and thus information flow from a significant number of input nodes to output nodes are disrupted. For the second network, the input-hidden layer bipartite graph is an expander, while the hidden-output layer bipartite graph is not an expander.

Here few of the flow paths from input to the output nodes are disconnected. Both the bipartite graphs for the third network are expanders, thus all the inputs nodes are connected to all the output nodes. We denote the first network as a disconnected one, the second network as partially connected, and the third one as fully connected. The example illustrates that layer-wise sparse bipartite expander graphs ensures global information flow across layers. While connected but non-expander sparse bipartite layers do not necessarily lead to global connectivity across layers. It is known in literature that sparse but resiliently connected neural networks not only have good generalization performance but also achieve noise robustness (Liu et al., 2018).

4.1. Bipartite Graph Structure

In this work, we focus on the fully-connected layers, and convolution layers of the feed-forward neural network only. Since, pruning is a part of network compression, we only consider the trainable layers here. We consider both unweighted and weighted representations of the bipartite graphs. We ignore signs of the weight values and consider only the magnitudes for the weighted graph representation. Even though sign of the weights are important for determining the neural network functionality, we argue that for studying their connectivity properties only the magnitudes need to be considered.

**Fully Connected Layers (FC):** For a fully connected layer \( N_i \) with \( n_i^{-1} \) number of inputs and \( n_i \) number of outputs the weighted bi-adjacency matrix of the corresponding graph is \( W_i \in \mathbb{R}^{[n_i^{-1} \times n_i]} \), and the corresponding pruning mask is \( M_i \in \{0, 1\}^{[n_i^{-1} \times n_i]} \).

**Convolution Layers (Conv):** Here, we consider the kernel size, the number of input and output channels to unfold the layer into a complete bipartite graph. For a convolution layer \( N_i \) with the kernel of size \( k \), \( n_i^{-1} \) input, and \( n_i \) output channels, the weighted bi-adjacency matrix of the corresponding graph will be \( W_i \in \mathbb{R}^{[(n_i^{-1} \times k) \times n_i]} \), and the corresponding pruning mask is \( M_i \in \{0, 1\}^{[(n_i^{-1} \times k) \times n_i]} \). An example is shown in Figure 2.

![Figure 2](image2)

**Figure 2.** An example of bipartite graph computation for a particular convolution layer with kernel size \( 2 \times 2 \), 2 input channels, and 3 output channels.

**Spectral Bounds for the Adjacency Matrix:** Now, the bounds are analyzed for both unweighted \((M_i)\) and weighted \((W_i)\) bipartite graphs at each layer \( N_i \). Table 1 describes different bounding constraint depending on the type of the considered graph and bound type. We consider the bound differences \((\Delta S \text{ and } \Delta R)\) for the eigenvalue and average degree respectively. The differences are divided by \( t_2 \) to make it comparable for different sized of bipartite graphs. A transition of the \( \Delta \) values from positive to negative denotes a violation of the bounds, and thus loss of Ramanujan graph property of the bipartite graph for the corresponding pair of layers in the feed-forward network.

4.2. Ramanujan Graph Property Preserving Pruning Algorithm

In this section, we describe a modification of the iterative pruning algorithm that preserves the Ramanujan graph property of a pruned neural network. In iterative pruning algo-
We propose a modification to the above method. If a weight value is still amenable to pruning. It avoids further pruning of a particular layer. If the pruned network is not satisfied for a particular layer, we consider a weighted graph with score function values as the edge weights. The bounds using the eigenvalues of this weighted graph is used to verify the spectral expansion property for a particular layer. If the pruned network $N_i^{temp}$ follows the Ramanujan graph property given by the bounds, then the algorithm simply proceeds to the next level of pruning operation. If the bound is not satisfied for a particular layer $i$, the weights are simply reset to the values before pruning and the pruning percentile $p$ is halved and search for a better approximation of $N_i$ is resumed. The target pruning level $k \in [K]$ is a controlling parameter to limit the search iteration. The proposed algorithm attempts to preserve Ramanujan property for as many layers as possible by using the spectral bound criteria to determine the layers which are still amenable to pruning. It avoids further pruning of the layers that have lost their connectivity property.

The method is described in Algorithm 1. It takes the trained network $N$, score function $\theta$, pruning percentile $p$, pruning level $K$ as inputs and returns the pruned network $N^*$. This algorithm is called at each pruning iteration, and continued till the stopping criterion is met, i.e., $N^*_i = N_i$, $\forall i$. As discussed in Section 3, we mainly study two types of bounds on the second largest eigenvalue of the bipartite graph $t_2 = \ell(G)$, i.e., (i) eb-based on the largest eigenvalue($t_1$) and (ii) db-based on the average degree ($d_{avgL}$ and $d_{avgR}$). We have considered $\max(\Delta_S, \Delta_R)$ to be greater than zero to define loss of the Ramanujan graph property (Hoory, 2005). To allow further pruning, we have checked whether the weighted graph follows the Ramanujan graph property using eigenvalue-bound $\Delta^\theta$ and the largest eigenvalue $t_1^\theta$ for the network weights. In order to avoid ‘layer collapse’ we stop pruning for a layer if the bipartite graph has a node with degree less than two.

The top-2 largest magnitude eigenvalues at layer $i$ are computed from the symmetric matrix $N_i^T N_i$ with implicitly restarted Arnoldi methods (Lehoucq et al., 1998) and, the average degree is computed from the connected component of the bipartite-graph. Hence, the computational complexity is mainly driven by the pruning level $K$, the number of input and output neurons at each layer, and the number of layers. The additional space will be required to store the bipartite graph.

graph of a layer. For the convolutional layers the size of the adjacency matrix is effectively same as the size of the convolution kernel which is usually small. Also, usually the number of fully connected layers are not very high.

5. Experimental Results

We have used the MNIST and CIFAR10 datasets in our study. As an evaluation measure we use the classification accuracy for both clean and noisy test sets. Noisy test sets were generated by adding zero mean $\sigma$ variance Gaussian noise to the image pixels. We report results for the Lenet, and Conv4 network architectures following the methodology adopted in (Frankle & Carbin, 2019). We also perform the studies on other networks which are presented in the Appendix. Hyper-parameter values are reported in Table 2.

5.1. Experimental Setup

We study the variation of classification accuracy with the network density as measured by the remaining weights percentile $100 - p$, where $p$ is the pruning percentile. For different layers the percentile can be different, as denoted by $p_{fc}$ for fully connected (FC) layers, $p_{conv}$ for convolution layers, and $p_{out}$ for output layers. We study the two cases for the bound specific to unweighted ($M_i$) and weighted graph ($W_i$). For each of the studies, we plot four parameters; (i) eigenbound bound difference ($\Delta_R$), (ii) average degree bound difference ($\Delta_S$), (iii) network density for each layer, and (iv) test accuracy on both clean and noisy data. The degree and eigenbound differences are defined in Table 1.

5.2. Relationship between the Ramanujan Graph Property and LTH

The primary goal of our study is to identify the LTH regimes, determined by the spectral properties of the bipartite-network layers. The existence of LTH regime is illustrated for two representative established networks. The results for Lenet on MNIST dataset is shown in Figure 3; and for Conv4 on CIFAR10 is shown in Figure 4. In each of the plots, we show the variation of classification accuracy on clean and noisy test sets (having various noise levels ($\sigma$)), with network density. The spectral properties are characterized by eigenbound difference $\Delta_S$ for both the weighted and unweighted graph representations, and the degree bound difference $\Delta_R$ for only the unweighted graph representation. A transition of $\Delta_S$ and $\Delta_R$ from positive to negative values denotes the loss of Ramanujan graph property of the corresponding layer bipartite graph. Accordingly, the plot is divided into three regimes - (i) fully Ramanujan, where all the layers maintain the Ramanujan property i.e., $\Delta > 0, \forall N_i$, (ii) partially Ramanujan, where some of the layers maintain the property, and (iii) non-Ramanujan, where none of the layers retain the property. For the Conv4 network which has more number of layers we show results for the unweighted graph representation only. Similar results for other networks and different pruning settings are discussed in the Appendix.

In all the figures, we observe that the accuracy values start dropping sharply beyond the partially Ramanujan graph property boundary (pink shade) when all the layers lose their Ramanujan graph property. Accuracy also starts reducing slowly from the fully Ramanujan boundary (gray shade). The accuracy on clean data falls sharply when the layers do not satisfy the bounds for the weighted graphs. The bounds for the unweighted graph allow only the robust winning tickets, having high accuracy even on noisy data. For very low network densities it is seen that the $\Delta$ values become positive again. This is a boundary effect owing to the in-applicability of Ramanujan graph bounds for disconnected graphs. We also add the fact that the accuracy doesn’t drop sharply can be attributed to two reasons. (1) The Ramanujan bound is optimal for a sequence of finite graphs going to infinity. Thus, the larger each bipartite layer is, the more accurately it is depicted. (2) Instead of considering the whole network as a Ramanujan graph, we are considering each bipartite layer as one and then computing the stopping criteria based on this. A drop in accuracy is indeed detected from the start of the pink region (where one layer loses the Ramanujan graph property) to the end (where all the layers lose it). The statistical significance of the relation between the Ramanujan Graph Property and LTH is discussed in Appendix.

5.3. Comparison of Pruning Approaches

We show that consideration Ramanujan graph properties benefits network pruning algorithms. We consider three popular network pruning algorithms - (i) Iterative Magnitude Pruning (IMP) (Frankle & Carbin, 2019), (ii) the iterative version of Single-shot Network Pruning based on Connection Sensitivity (SNIP) (Lee et al., 2018), (iii) Synaptic flow based pruning SynFlow (Tanaka et al., 2020) and show the results of test accuracy achieved with similar densities with and without the bound condition. To do this experimentation, we choose the a fix compression ratio $\alpha$.
to achieve the desired density of the pruned network as $10^{-\alpha} \times 100$, and observe the difference in accuracy due to the network connectivity. The results are presented in Table 3 for Lenet/MNIST and Conv4/CIFAR10. For each of the algorithm we consider three cases - (i) the network is pruned to very low densities using existing algorithms, (ii) network pruning is stopped when there is loss of Ramanujan graph properties (#AlgoName-Bound), and (iii) the existing algorithm is compared with the target density achieved by applying case-ii (#AlgoName*). The bounds are considered as two types of bounds - first it tries to maintain the bounds on the unweighted graph. Next, if the unweighted graph loses the Ramanujan property it tries to preserve the information flow by considering the spectral bounds for the weighted graphs with score function. We use layer-wise pruning for all the algorithms.

Here, adding the bound criteria guides the pruning algorithm to stop at a density where the accuracy is comparable with its original network. For all the algorithms at same density (typically very low) the addition of bounding cri-
6. Related Work

Neural network pruning involves sparsification of the network (LeCun et al., 1990; Blalock et al., 2020). It identifies the weight parameters, removal of which incurs minimal effect on the generalization error. There exists different categories of pruning based on (i) how the pruning is performed, for instance based on the weight magnitude (Han et al., 2015; Zhu & Gupta, 2017), gradient in the backpropagation, hessian of the weight (Hassibi et al., 1993; Dong et al., 2017; Lee et al., 2018), etc; (ii) whether the pruning is global or local; (iii) how often pruning should be applied like one-shot (Lee et al., 2018; Wang et al., 2020), iterative (Tanaka et al., 2020). One of the primary goals in the literature has been to reduce the computational footprint at the time of prediction, i.e., during post-training. In recent LTH studies, the victim weights are determined by their value at the initialization, gradient of the error, and network topology (Lee et al., 2019; Tanaka et al., 2020). To understand weight initialization, (Malach et al., 2020) show that pruning makes a stronger hypothesis with bounded weight distribution. The sparsity of the network is reduced from polynomial to a logarithmic factor of the number of training variables (Orseau et al., 2020). Recently, the deep-expander networks and their block sparse approximations are introduced for getting better sparse network (Prabhu et al., 2018; Vooturi et al., 2021). (Mocanu et al., 2018) suggest to consider the topology of the network from a network science point of view. The pruning algorithm starts from a random Erdős Rényi graph and returns a scale-free network of a high sparsity factor based on the number of neurons in each layer. The method is further evolved for CNN layers considering both the magnitude and gradient of the weights (Evci et al., 2020a).

### 7. Conclusion

In this work, we study the validity of the lottery ticket hypothesis (LTH) based on structural connectivity properties of the neural network. Ramanujan graph properties of the bipartite layers are studied in terms of certain spectral bounds. As test accuracy varies with decreasing network density as a result of pruning, three distinct regions are demarcated using these bounds. In the first region, all the bipartite layers are Ramanujan graphs, in the second region some of them are, and in the third low network density regions none of the layers are Ramanujan graphs. We empirically demonstrate the validity of the lottery ticket hypothesis robustly in the first region and partially in the second region. We propose a modification of existing iterative pruning algorithms that preserves Ramanujan graph property. Further refinement of this approach of pruning can result in more efficient winning ticket search, which will be the basis of future research.

A. Appendix

We present additional results to supplement those given in the paper. We have used the code from https://github.com/facebookresearch/open_lth to generate all the results for LTH explanation. For the experiment of comparison of different pruning algorithms, we have modified the code from https://github.com/ganguli-lab/Synaptic-Flow. The results for corresponding to the LTH hypothesis is presented. Then detailed results concerning the pruning algorithms are described.

A.1. More Results for Lenet Architecture on MNIST Dataset

Here, we study different pruning scheme of IMP to understand the Ramanujan characteristic of the bipartite graph in each layer and its relation to the classification performance in terms of accuracy.

A.5. The Statistical Significance of the Relation between the Ramanujan Graph Property and LTH

We have performed statistical significance tests for the zero crossing of $\Delta$ values. At every pruning iteration, we compute the $\Delta$ values at each layer for 10 different runs. We test the null hypothesis $H_0: \max(\Delta_S, \Delta_R) \geq 0$ and the alternate hypothesis $H_1: \max(\Delta_S, \Delta_R) < 0$. A t-test is performed with a confidence level 0.95, and the upper and lower mean value are computed for both the architectures in Table 4 and 5, for MNIST/Lenet and CIFAR10/Conv4, respectively. As the variance of $\Delta_R$ or $\Delta_S$ depends largely on the network size and the weights, the upper and lower bound of the mean value will help in deciding the stopping point of further pruning for different layers. In Figures 3 and 4, the gray region corresponds to the pruning iterations where for all the layers the null hypothesis $H_0$ is significant. For the pink and the white regions the null hypothesis is true for some and none of the layers respectively. Similarly, at every pruning iteration we test the drop of accuracy as compared to the unpruned network. Let $a_0$ and $a_t$ be the test accuracy of the unpruned network and the network at pruning iteration $t$ respectively. We test the null hypothesis $H_0: a_0 - a_t \leq k$. A t-test is again performed. We observe that for $k = 0.001$ the null hypothesis is significant in the gray region, and for $k = 0.01$ in the pink region for MNIST/Lenet. We also observe that same for CIFAR/conv4 with different values of $k$. Here, for $k = 0.01$ the null hypothesis is significant in the gray region, and for $k = 0.05$ in the pink region for CIFAR/conv4. Thus the statistical significance of the relation between Ramanujan graph property and LTH is established.

A Study on the Ramanujan Graph Property of Winning Lottery Tickets

A.6. Importance of the Ramanujan Graph Property in Designing Pruning Algorithms

Here, we show the result in support of the importance of the Ramanujan Graph property in the sparse sub-graph of the lottery ticket. As more number of layers start losing this property the network is prone to observe impact in its performance. We show the comparison of accuracy and the number of layers lose the Ramanujan Graph property (in same density) for two pruning Algorithms, IMP, and Synflow in Figure 14. We see the result for Conv4/CIFAR10. With density of 3.16 the IMP achieves accuracy of 60.61% while SynFlow meets 77.18% accuracy. By analyzing the detail it has been found that the Ramanujan property is lost in FC layer-1 only for SynFlow where the same is observed in IMP for both Conv Layer-4 and FC layer-1. Hence, we can infer that a better pruning algorithm or a winning ticket must have the maximum possible layers in preserving the Ramanujan graph property.
