Gate-dependent spin–orbit coupling in multielectron carbon nanotubes

T. S. Jespersen\textsuperscript{1,\ast,†}, K. Grove-Rasmussen\textsuperscript{1,2,\dagger}, J. Paaske\textsuperscript{1}, K. Muraki\textsuperscript{2}, T. Fujisawa\textsuperscript{3}, J. Nygård\textsuperscript{1} and K. Flensberg\textsuperscript{1}

Understanding how the orbital motion of electrons is coupled to the spin degree of freedom in nanoscale systems is central for applications in spin-based electronics and quantum computation. Here we demonstrate such spin–orbit coupling in a carbon-nanotube quantum dot in the general multielectron regime and in the presence of finite disorder. Also, we find a systematic dependence of the spin–orbit coupling on the electron occupation of the quantum dot. Such a dependence has not been seen in any other system and follows from the curvature-induced spin–orbit-split Dirac spectrum of the underlying graphene lattice. Our findings suggest that the spin–orbit coupling is a general property of carbon-nanotube quantum dots, which should provide a unique platform for the study of spin–orbit effects and their applications.

The interaction of the spin of electrons with their orbital motion has become a focus of attention in quantum-dot research. On the one hand, this spin–orbit interaction (SOI) provides a route for spin decoherence, which is unwanted for purposes of quantum computation\textsuperscript{1–5}. On the other hand, if properly controlled, the SOI can be used as a means of electrically manipulating the spin degree of freedom\textsuperscript{6–7}.

In this context, carbon nanotubes (CNTs) provide a number of attractive features, including large confinement energies and nearly nuclear-spin-free environment; most importantly, the details of the energy-level structure are theoretically well understood and modelled, as well as being experimentally highly reproducible. Remarkably, the SOI in nanotubes was largely overlooked in the first two decades of nanotube research and was only recently demonstrated by Kuemmeth \textit{et al.} for the special case of one and two carriers in ultraclean CNT quantum dots\textsuperscript{8,9}. Except for these reports, the SOI in nanotubes is experimentally unexplored. Theoretically, the focus has exclusively been on the SOI-modified band structure of disorder-free nanotubes\textsuperscript{10–14}. Therefore, two important questions remain: how the effective SOI depends on electron filling and how it appears in the general case of quantum dots subject to disorder. Here we answer these two questions.

First, by low-temperature electron transport we demonstrate the presence of a significant SOI in a disordered CNT quantum dot holding hundreds of electrons. We identify and analyse the role of SOI in the energy spectrum for one, two and three electrons in the fourfold degenerate CNT electronic shells, thus describing shells at any electron filling. By rotating the sample, we present spectroscopy of the same charge states for magnetic fields both parallel and perpendicular to the nanotube axis, thus controlling the coupling to the orbital magnetic moment. Remarkably, a single-electron model taking into account both SOI and disorder quantitatively describes all essential details of the multielectron quantum-dot spectra. Second, by changing the electron occupancy we are able to tune the effective SOI in accordance with the expected curvature-induced spin–orbit splitting of the underlying graphene Dirac spectrum\textsuperscript{11–14}. Such systematic dependence has not been demonstrated in any other material system and may enable a new range of spin–orbit-related applications. This microscopic understanding and detailed modelling is in stark contrast to situations encountered in alternative strong-SOI quantum-dot materials, such as InAs or InSb nanowires, where the effective SOI arises from bulk crystal effects combined with unknown contributions from surface effects, strain and crystal defects\textsuperscript{15}. These systems often exhibit semi-random fluctuations of, for example, the $g$-factor as single electrons are added\textsuperscript{16,17}. Thus, beyond fundamental interest and the prospect of realizing recent proposals of SOI-induced spin control in CNTs (refs 1, 18), our findings pave the way for new designs of experiments using SOI in quantum dots.

\textbf{Breaking the fourfold degeneracy}

Our experimental set-up is presented in Fig. 1a. We fabricate devices of single-wall CNTs on highly doped Si substrates capped with an insulating layer of SiO\textsubscript{2} (see the Methods section). The size of the quantum dot is defined by the contact separation (400 nm) and the electrical properties are investigated in a voltage-biased two-terminal configuration, applying a voltage $V_\text{sd}$ between source and drain contacts and measuring the resulting current $I$. The differential conductance $\text{d}I/\text{d}V_\text{sd}$ is measured by standard lock-in techniques. When biased with a voltage $V_g$, the Si substrate acts as an electrostatic gate controlling the electron occupancy of the dot. The device is measured at temperature $T = 100 \text{ mK}$ in a $^3\text{He}/^4\text{He}$ dilution refrigerator, fitted with a piezo-rotator enabling in-plane rotations of the sample in magnetic fields up to 9 T.

Figure 1b shows a typical measurement of $\text{d}I/\text{d}V_\text{sd}$ versus $V_\text{sd}$ in the multielectron regime of a small-bandgap conducting nanotube. The pattern of diamond-shaped regions of low conductance is expected for a quantum dot in the Coulomb blockade regime, and within each diamond the quantum dot hosts a fixed number of electrons $N$, increasing one by one with increasing $V_g$. The energy $E_\text{sd}$ required for adding a single electron is seen as the diamond heights and has been extracted in Fig. 1c. The

four-electron periodicity clearly observed in Fig. 1b,c reflects the near fourfold degeneracy in the nanotube energy spectrum\(^{19-23}\); one factor of two from the intrinsic spin (\(\uparrow, \downarrow\)) and one factor of two from the so-called isospin (K, K\(^\prime\)) that stems from the rotational symmetry of the nanotube—electrons orbit the CNT in a clockwise or anticlockwise direction. As is generally observed\(^{19-23}\), the addition energy for the second electron in each quartet (yellow in Fig. 1c) exceeds those for one and three. This was previously interpreted as a result of disorder-induced coupling \(\Delta_{kk}\) of the clockwise and anticlockwise states\(^{21,24}\) that splits the spectrum into two spin-degenerate pairs of bonding/antibonding states separated by \(\Delta_{kk}\). As mentioned, Kuemmeth \textit{et al.} recently showed that for the first electron in an ultraclean suspended nanotube quantum dot the splitting was instead dominated by the spin–orbit coupling. The first question we address here is whether SOI also appears in the many-electron regime and how it may be modified or masked by disorder.

### Modelling spin–orbit coupling and disorder

Carrying out level spectroscopy with a magnetic field \(B\) applied either parallel (\(B_\parallel\)) or perpendicular (\(B_\perp\)) to the nanotube axis proves to be a powerful tool to analyse the separate contributions from disorder and spin–orbit coupling. This is illustrated in Fig. 2a–d, which shows calculated single-particle energy-level spectra for four limiting combinations of \(\Delta_{kk}\) and the effective spin–orbit coupling \(\Delta_{so}\) (all limits are relevant for nanotube devices depending on the degree of disorder and CNT structure\(^{3,14}\); details of the model are provided in Supplementary Information). In all cases a parallel field separates the four states into pairs of increasing (K-like states) and decreasing (K\(^\prime\)-like states) energies. The magnitude of the shift is given by the orbital g-factor \(g_\text{orb}\) reflecting the coupling of \(B_\parallel\) to the orbital magnetic moment caused by motion around the CNT (ref. 25). Further, each pair exhibits a smaller internal splitting owing to the Zeeman effect. Figure 2b shows the disorder-induced coupling of K and K\(^\prime\) states resulting in an avoided crossing at \(B_\parallel = 0\) and the zero-field splitting discussed above. In the opposite limit with SOI only (Fig. 2c), the zero-field spectrum is also split into two doublets, but the field dependence is markedly different and no avoided crossing appears. In the simplest picture, this behaviour originates from coupling of the electron spin to an effective magnetic field \(B_{so} = -(v \times E)/c^2\) experienced by the electron as it moves with velocity \(v\) in an electric field \(E\). Here the speed of light, \(c\), reflects the relativistic origin of the effect. In nanotubes, the curvature of the graphene lattice generates an effective radial electric field, and as the velocity is mainly circumferential (and opposite for K and K\(^\prime\)), \(B_{so}\) polarizes the spins along the nanotube axis and favours parallel or antiparallel alignment of the spin and orbital magnetic momentum depending on the sign of \(\Delta_{so}\). Thus, even in the absence of disorder, the spectrum splits into two Kramers doublets (K \(\uparrow\), K\(^\prime\) \(\uparrow\)) and (K \(\downarrow\), K\(^\prime\) \(\downarrow\)) separated by \(\Delta_{so}\). Interestingly, as a perpendicular field does not couple K and K\(^\prime\) the doublets do not split along \(B_\parallel\) (Fig. 2c). As a consequence, the g-factor, when measured in a perpendicular magnetic field, will vary from zero when \(\Delta_{so} \gg \Delta_{kk}\) (Fig. 2c) to two in the opposite limit (Fig. 2b; ref. 26).

The final case, including both disorder and SOI, is of particular importance for the present study, and the calculated spectrum...
Spin–orbit interaction revealed by spectroscopy

With Fig. 2 in mind, we now focus on the quartet with \( 4N_0 \approx 180 \) electrons highlighted in Fig. 1b and expanded in Fig. 3a. To investigate the level structure we carry out cotunnelling spectroscopy, as illustrated in the schematic Fig. 3b (ref. 27): in Coulomb blockade, whenever \( e|V_{sd}| \) matches the energy of a transition from the ground state \( \alpha \) to an excited state \( (\beta, \gamma, \delta) \), inelastic cotunnel processes, which leave the quantum dot in the excited state, become available for transport. This significantly increases the current and gives rise to steps in the conductance. These appear as gate-independent features in Fig. 3a (arrows) and are clearly seen in the inset, showing a trace through the centre of the one-electron \( (4N_0 + 1) \) diamond along the dashed line. Thus following the magnetic-field dependence of this trace, as shown in Fig. 3c, maps out the level structure. The energies of the excitations are given by the inflection points of the curve (that is peaks/dips of \( d^2I/dV_{sd}^2 \); ref. 28) and the level evolution is therefore directly evident in Fig. 3d–i, which shows colour maps of the second derivative versus \( V_{sd} \) and \( B_{||} \) for \( V_f \) positioned in the centre of the one-, two- and three-electron charge maps of the second derivative versus \( V_{sd} \) and \( B_{||} \) for \( V_f \).
states. As explained below, the SOI is clearly expressed in all three spectra.

Consider first the one-electron case: in a parallel field (Fig. 3d) the asymmetric splitting of the two doublets is evident (black versus green arrows), and applying the field perpendicularly (Fig. 3g) the SOI is directly expressed as the avoided crossing indicated in the figure. The measurement is in near-perfect agreement with the single-particle excitation spectrum calculated by subtracting the energies of Fig. 3b and shown by the solid lines. The calculation depends on only three parameters: $\Delta_{SO} = 0.15 \text{ meV}$ set directly by the avoided crossing, $\gamma = 0.45 \text{ meV}$ determined from the zero-field splitting of the doublets (see Fig. 2d), and $g_{ub} = 5.7$ set by the slopes of the excitation lines from $\alpha$ to $\gamma, \delta$ in $d$.

Consider now the role of SOI for the doubly occupied CNT quartet. This situation is of particular importance for quantum computation as a paradigm for preparation of entangled states. As explained below, the SOI is clearly expressed in all three spectra.

Finally, the spectrum of three electrons in the four-electron shell is equivalent to that of a single hole in a full shell; at low fields the $\delta$-state becomes the ground state and $\gamma$ the first excited state, whereas $\alpha$ and $\beta$ then constitute the excited doublet. As seen by comparing Fig. 2b,d SOI breaks the intra-shell electron–hole symmetry of the nanotube spectrum. This is evident in the experiment when comparing Fig. 3d,f; in 3f, increasing $B_{\parallel}$, the lowest excited state $\gamma$ barely separates from the ground state $\delta$ and at $B_{\parallel} = 1.1 \text{ T}$ they cross again, causing a ground-state transition. At the crossing point, the spin-degenerate ground state results in a zero-bias Kondo peak (see inset)\textsuperscript{31}. Interestingly, this degeneracy also forms the qubit proposed in ref. 1. For the $B_{\parallel}$ dependence the one- and three-electron cases remain identical and Fig. 3i exhibits again the SOI-induced avoided crossings.

**Gate-dependent spin–orbit coupling**

Having established the presence of SOI in the general many-electron disordered quantum dot, we now focus on the dependence of $\Delta_{SO}$ on the quantum-dot occupation. To this end, we have repeated the spectroscopy of Fig. 3 for a large number of CNT quartets and in each case extracted $\Delta_{SO}$ by fitting to the single-particle model (all underlying data are presented in Supplementary Information). Interestingly, quartets in the valence band have the one- and three-electron spectra qualitatively reversed compared with Fig. 3; thus, although SOI favours parallel spin and orbital magnetic moments in the conduction band, it favours antiparallel polarization for electron states in the valence band. Thus in this sense electron–hole symmetry is preserved, corresponding to positive $\Delta_{SO}$ for both the valence and conduction bands. This contrasts the situation of Kuemmeth et al.\textsuperscript{37} and is surprising, as electron–hole symmetry is broken in the conventional picture of SOI as acting equivalently to an effective parallel magnetic field. Figure 4a shows the resulting gate dependence of $\Delta_{SO}$. A gradual decrease is observed as electrons are added to the conduction band and the values exceed those of the valence band at the same electron/hole filling. This agrees qualitatively with recent models of the curvature-induced spin–orbit splitting of the underlying graphene lattice, as we now discuss.

The magnitude of $\Delta_{SO}$ is given by the spin–orbit splitting of the underlying graphene band structure. For flat graphene this splitting is very weak ($\Delta_{SO}^{\text{graphene}} \sim 1 \text{ meV}$; ref. 12), as it is second order in the already weak atomic SOI of carbon $\Delta_{SO} \sim 8 \text{ meV}$. In nanotubes,
however, the curvature induces a coupling between the $\pi$- and $\sigma$-bands and generates a curvature-induced spin–orbit splitting, which is first order in the atomic SOI and thus greatly enhances $\Delta_{SO}$. Around a Dirac point of the Brillouin zone (for example K), the graphene band structure appears as in Fig. 4b (refs 11–14): the spin-up and spin-down Dirac cones are split by SOI both in energy and along $k_z$, the momentum in the circumferential direction of the CNT. The schematic diagram in Fig. 4c also highlights the CNT $\Delta_{SO}$ and accounts for the band, which are illustrated in Fig. 4d. For the nanotube studied in ref. 8 (semiconducting, small bandgap). Typically CVD-grown single-wall CNTs demonstrate the opposite limit of dominating $\Delta_{SO}$ due to the larger filling. The measured gate dependence of $\Delta_{SO}$ thus qualitatively agrees with the spin–orbit splitting of the graphene Dirac spectrum caused by the curvature of the nanotube, and fitting to equation (1) (Fig. 4a, dashed line) yields $\Delta_{SO} = 40 \pm 15$ meV and $\Delta_{SO} = -170 \pm 15$ meV. Band-structure models relate these parameters to the structure of the nanotube23–25: $\Delta_{SO} = (\alpha/\beta) \Delta_{G} \Delta D$ and $\Delta_{SO} = -\alpha \Delta_{G} \Delta D$, where $D$ is the nanotube diameter and $\alpha, \beta$ constants that depend on the CNT class (semiconducting, small bandgap). Typically CVD-grown single-wall CNTs have diameters in the range 1–3 nm, whereas obtaining $D$ from the measured values of $\Delta_{SO}$ gives $D \approx 10$ nm. Thus taking $D = 1–10$ nm we estimate $(\alpha/\beta) \approx (0.2–6) \times 10^{-4}$ (nm meV)$^{-1}$ and $\alpha \approx (0.02–0.3)$ nm. Although $\alpha$ is consistent with the value quoted in the theoretical literature (0.048 nm; ref. 14), the predicted $(\alpha/\beta)$ value $-2 \times 10^{-3}$ (nm meV)$^{-1}$ does not match the experimental value or sign. This sign reflects whether the valence or conduction band experiences the higher spin–orbit splitting: for small-bandgap nanotubes theory predicts the valence-band spin–orbit splitting to exceed the conduction-band value14,33— inconsistent with the present measurement and ref. 8. The origin of this discrepancy remains unknown, and work on SOI in nanotubes with known chirality is needed to make further progress.

The methods

The devices are made on a highly doped silicon wafer terminated by 500 nm of SiO$_2$. Alignment marks (70 nm) are defined by electron-beam lithography before deposition of catalyst islands made of iron nitrate (Fe(NO$_3$)$_3$)·9H$_2$O acetate and alumina support particles18. The sample is then transferred to a furnace, where single-wall carbon nanotubes are grown by chemical vapour deposition at 850–900 °C in an atmosphere of hydrogen, argon and methane gases. Pairs of electrodes consisting of Au/Pt (40/10 nm) spaced by 400 nm are fabricated alongside the catalyst islands by standard electron-beam lithography techniques. Finally, bonding pads (Au/Cr 150/10 nm) are made by optical lithography and the devices are screened by room- and low-temperature measurements.

We measured the sample in an Oxford dilution refrigerator fitted with an Attocube ANRv51 piezo rotator, which enables high-precision in-plane rotation of the sample in large magnetic fields. The rotator provides resistive feedback of the actual position measured by lock-in techniques. For electrical filtering, room-temperature $\pi$-filters and low-temperature Thermocoax are used. The base temperature of the modified refrigerator is around 100 mK; all measurements are broadened by tunnel coupling, not temperature. The CNT measurement set-up consists of a National Instrument digital-to-analogue card, custom-made optically coupled amplifiers, a DIL Instruments 1211 current-to-voltage amplifier and a Princeton Applied Research 5210 lock-in amplifier. Standard d.c. and lock-in techniques have been used to measure current and differential conductance $dI/dV$ at $T \approx 0$ mK.

The bandgap of the device $2\Delta_{SO} \approx 30$ meV is measured directly as a large Coulomb peak at $V_g \approx 1$ V, and in fitting the data of Fig. 4a to equation (1) we used $\varepsilon_{so} \approx 25$ meV/V$\times$V, estimated from the level spacing $\Delta E \approx 3$ meV and the average Coulomb peak spacing $(\Delta V) \approx 30$ mV.
