Low-temperature three-terminal transport measurements through a thiol end-capped \( \pi \)-conjugated molecule have been carried out. Electronic excitations, including zero and finite-bias Kondo-effects, have been observed and studied as a function of magnetic field. Using a simplified two-orbital model, we have accounted for the spin and the electronic configuration of the first four charge states of the molecule. The charge-dependent couplings to gate, source, and drain electrodes suggest a scenario in which charges and spins are localized at the ends of the molecule, close to the electrodes.
delocalised \(\pi\)-electron system, this derivative has \(n\)-C\(_{12}\)H\(_{25}\) side arms to make it soluble and acetyl protected thiol endgroups to ensure bonding with the gold electrodes. Electromigration was performed on a 10 nm thick gold wire with a width of 100 nm and a length of 500 nm (see also Figure 1b) using a recently developed self-breaking method. Molecule deposition was done from solution as described in ref 23.

The transport measurements are represented in Figure 2a as a plot of the differential conductance as a function of applied bias and gate-voltage. Similar to the well-established bias/gate-spectroscopy of semiconducting and nanotube quantum dots, we observe crossing bright lines separating regions of high conductance (single-electron tunneling (SET) regime) from enclosed diamond-shaped black regions with very low conductance. Horizontal, slightly dimmer, lines within these regions are due to higher-order tunneling processes.

The overall structure of the bright slanted lines reveals three crossing points, separating four different charge states of the molecule. Numbers in Figure 2b indicate the charge states (see discussion below). Zero-bias Kondo resonances are visible in the \(N = +1\) and \(+3\) charge states; the \(N = +2\) state reveals two finite-bias resonances located symmetrically around zero bias. The sequence single peak, split peak, single peak is highlighted in Figure 2b and shows a striking resemblance to data on carbon nanotube quantum dots. Another characteristic feature of the Coulomb diamonds is an addition energy of 65 ± 5 meV for \(N = +1\) and of 115 ± 5 meV for \(N = +2\), similar to earlier reports on the same molecule. The crossing between \(N = +1\) and \(+2\) is of particular interest and Figure 2c shows a high-resolution dI/dV map of this region. On the right-hand-side the zero-bias Kondo peak is clearly visible; on the left-hand-side there are two peaks at a bias voltage of ±1.7 mV. Examples of differential conductance traces for both cases are plotted in Figure 2f. The very small peaks superimposed on the main peaks are believed to be vibrational side bands at energies comparable to those measured in other samples. They are also faintly present in the SET regime.

Inspection of the data in Figure 2c also shows an excitation running parallel to the \(N = +2\) diamond edge which exhibits negative differential resistance (NDR as illustrated in Figure 2e, upper trace). In Figure 2c the energy of this excitation can be read off as the distance from the zero-bias axis to the crossing point with the diamond edge; it equals 6 ± 1 meV. At the negative side, this excitation is also present at the

Figure 1. (a) Schematic device lay-out and artistic impression of an OPV-5 molecule bonded to two gold electrodes. (b) Fabricated device prior to breaking the small gold wire in the middle by electromigration. The junction is fabricated on top of an aluminum gate electrode, which is oxidized in air to form a 2 to 4 nm thick Al\(_2\)O\(_3\) layer and at low temperatures, substantial leakage currents are typically observed for voltage above ±4 V. Bridges are electromigrated at room temperature by ramping a voltage until a decrease in the conductance is observed, upon which the applied voltage is returned to zero; the cycle is repeated until a target resistance has been reached. (c) Molecular structure of OPV-5.
same energy as a zero-bias conductance plateau. For the \( N = +2 \) state, excitations are present at \( 30 \pm 1 \) and \( 37 \pm 1 \) meV.

We have studied the low-bias features of Figure 2c as a function of temperature and magnetic field. The temperature dependence of the maximum conductance of the peaks at \( N = +1 \) and +3 is consistent with the regular \( S = \frac{1}{2} \) Kondo effect as shown in Figure 3b by the red lines which are fits to the expected behavior

\[
G_K = G_c + G_a \left[ 1 + (2^{1/s} - 1) \frac{\hbar^2}{T K_c^2} \right]^{-s} \tag{1}
\]

where \( s = 0.22 \) and where \( G_c \) and \( G_a \) are fitting parameters. The fits yield Kondo temperatures of 37 and 30 K for \( N = +1 \) and +3, respectively, roughly consistent with the full width at half-maximum of the zero-bias peaks which are 32 K for \( N = +1 \) and 24 K for \( N = +3 \). For \( N = +2 \), the zero-bias conductance first increases as the temperature is raised. At 35 K, it reaches a maximum, and for higher temperatures, the conductance decreases again. The value of 35 K corresponds to an energy of 3 meV, which is close to the distance between the split low-bias peaks in this charge state (see Figure 2f).

Figure 4, panels a and d, shows the conductance traces at gate voltages 0.56 V (\( N = +1 \)) and -0.72 V (\( N = +2 \)), respectively, for various magnetic fields. For \( N = +1 \), the magnetic field splits the peak in two and the magnetic field dependent data are again consistent with \( S = \frac{1}{2} \) Kondo physics. Measurements on the finite-bias peaks inside the \( N = +2 \) diamond show that a magnetic field splits each peak into two clear peaks. At negative bias, the third derivative (Figure 4f) shows the presence of three peaks. This evolution ensures that the other electronic levels are far away or are not involved in transport. At low-energy we do see lines in the second derivative, which we identify as vibrational modes. (c) Two \( dI/dV \) traces taken at different gate voltages; their position is indicated in (c) by thin vertical lines. The blue curve shows a negative differential resistance (NDR) effect at positive bias voltage. (f) \( dI/dV \) traces taken in the middle of the Coulomb diamonds of the charge states \( N = +2 \) and +1.

![Figure 2](image_url)

(a) Two-dimensional color plot of the differential conductance, \( dI/dV \), versus \( V \) and \( V_\text{G} \) at \( T = 1.7 \) K measured with a lock-in technique (modulation amplitude 0.4 mV). Minimum and maximum conductances are \(-5\) and \(+25\) \( \mu \)S respectively. Dotted green lines indicate the diamond edges of a second molecule connected in parallel. When transferring the probe into another dewar, this structure moved to a less negative gate voltage whereas the other three degeneracy points remained at the same location (see the Supporting Information, section S4). (b) Schematic drawing of the important information contained in (a) with the charge filling sequence as discussed in the text. (c) Zoom-in between charge states +2 and +1 exhibiting respectively finite-bias and zero-bias Kondo effects. (d) Schematic drawing of (c) highlighting its important features. Dashed lines are not visible in the contrast of (c) but do appear when adjusted. It is important to note that other strong excitations are not present, indicating that the other electronic levels are far away or are not involved in transport. At low-energy we do see lines in the second derivative, which we identify as vibrational modes. (e) Two \( dI/dV \) traces taken at different gate voltages; their position is indicated in (c) by thin vertical lines. The blue curve shows a negative differential resistance (NDR) effect at positive bias voltage. (f) \( dI/dV \) traces taken in the middle of the Coulomb diamonds of the charge states \( N = +2 \) and +1.

in a magnetic field, $\mathbf{B}$, is consistent with inelastic cotunnelling from a singlet ground state to an excited triplet (cf. Supporting Information, section S3). The splitting in each peak should be $g \mu_B B$ with $m_s = \pm 1$. With a $g$-factor of 2 the splitting in Figure 4e,f yields an $m_s$ value of 0.87 at negative bias and 1.0 at positive bias, consistent with the identification of the triplet state as the excited state.

From the magnetic field measurements, we conclude that the Coulomb diamond with the split peaks in zero-magnetic field has a ground state with an even occupancy. We assign $N = +2$ to this state, and starting from this, the electronic and spin spectrum can be identified using a model that involves two weakly interacting states with an antiferromagnetic exchange energy $J$. From standard Coulomb blockade theory, we employ the following effective Hamiltonian for the molecule (cf. refs 24 and 25)

$$H_{\text{mol}} = E_C \left( \sum_{i=1}^{N} n_{i\alpha} - N_0 - N_0 \right)^2 + \delta n_B + dU \sum_{\sigma = \uparrow, \downarrow} \sum_{i \neq j} n_{i\sigma} n_{j\sigma} + J \langle \mathbf{S}_A \cdot \mathbf{S}_B \rangle$$

where $\{n_{i\alpha}, n_{i\uparrow}, n_{i\downarrow}, \mathbf{S}_i \}$ denote the occupation operators for two distinct orbitals $A$ and $B$ with corresponding spin $1/2$ operators $\mathbf{S}_i$. The parameters represent an orbital splitting $\delta$, an electrostatic charging energy $E_C = e^2/2C$ defined in terms of a total capacitance $C$, a gate-induced charge $N_G = C_G V_G/e$, an additional intraorbital Coulomb repulsion $dU$ and an interorbital antiferromagnetic exchange-coupling $J > 0$.

From the Hamiltonian in eq 2, the addition and excitation energies can be calculated assuming that charging the molecule is merely a matter of filling up two distinct “frozen” orbitals. Figure 5a summarizes the results for the $N = +1$ and $+2$ charge states. We now compare the predictions of this model with the data and check for consistency. For $N = +2$, the data reveal a singlet ground state together with inelastic cotunnelling lines at $\pm 1.7$ meV ($E_{S_N}^{1}$), which are connected to a triplet state. Thus, the exchange coupling, $J$, is antiferromagnetic and equals 1.7 meV. The data at $N = +1$ show a strong excitation at $6 \pm 1$ meV, which we identify as the level mismatch $\delta$ ($E_{S_N}^{1}$). For the $N = +2$ state another excitation ($E_{S_N}^{2}$) is visible at $\pm 37$ meV. At the positive side, there is also an additional excitation at 30 meV connected to a transition between the second $N = +2$ excited-state and the first $N = +1$ excited state ($E_{S_N}^{1} - E_{S_N}^{1}$). The difference between these excitations at 30 and 37 meV should be the level mismatch $\delta$, which is indeed the case. The value of 37 meV for the second excitation for the doubly charged state indicates that $dU = 42 \pm 2$ meV. The experimental values for the addition energies are $E_{add, N = +1} = 65 \pm 5$ meV and $E_{add, N = +2} = 115 \pm 5$ meV. From the first number, we deduce a charging energy $E_C = 30 \pm 3$ meV, whereas the reading for $E_{add, N = +2}$ implies that $E_C = 38 \pm 4$ meV. The fact that these two numbers are close serves as a positive consistency check of our two-orbital model.

We emphasize that the analysis presented above accounts for all of the electronic and magnetic excitations of the OPV-5 junction throughout four consecutive charge states. The remaining question is how the two weakly interacting and spatially separated states $A$ and $B$ relate to the molecule in the junction. Here we note that the presence of two nearly degenerate antiferromagnetically coupled states corroborates a picture invoked in previous papers involving image charges in the metal electrodes in which charges and spins localize at either end of the molecule as schematically illustrated in Figure 5b.8,26 In the remainder of this letter, we highlight another feature of these states which hints at their molecular origin.

The line width defining the diamond-like structures in Figure 2a is proportional to the electronic coupling, $\Gamma$, and as this figure shows, appears to be dependent on the charge state: The diamond edges are sharper for the $N = +2$ state compared to $N = +1$ and $+3$. For the region where electron tunneling involves $0 \rightarrow +1 \rightarrow 0$ transitions, a Lorentzian fit through the $dI/dV$ vs $V$ line shape yields $\Gamma \approx 35$ meV; for the $+1 \rightarrow +2 \rightarrow +1$ and $+2 \rightarrow +3 \rightarrow +2$ transitions, $\Gamma = 6$ and 22 meV, respectively. A related observation is that the gate coupling for the three different charge states is not the same. For charge state $+1$, $+2$, and $+3$ the gate coupling equals 0.06, 0.1, and 0.07, respectively. Thus, the $N = +2$ charge distribution on the molecule is more susceptible to the gate field. Apparently, the wave functions are located...
more to the middle of the junction in agreement with the lower electronic coupling for this charge state.

By considering the plausible valence bond structures of OPV-5, we have been able to link the observed change with charge state in couplings to electrodes and gate to its molecular structure. For the first three positively charged states, these bond structures are depicted in Figure 6. The singly charged state (top) is a spin doublet with a strongly localized charge at one terminal. The spin remains localized to the same terminal benzene ring to preserve aromaticity (undisturbed benzene rings which are particularly stable) in the remaining four rings. Charge transport could occur by charges tunneling directly to and from this terminal state that hence defines the values of $\Gamma$ and the gate coupling.

The likely representation of the doubly charged state is shown in the middle of the figure where the ground state is represented by two states similar to the singly charged molecule, but with the possibility to mix the quinone state (undisturbed benzene rings which are particularly stable) in the remaining four rings. Charge transport could occur by charges tunneling directly to and from this terminal state that hence defines the values of $\Gamma$ and the gate coupling.

Figure 4. (a) $dI/dV$ trace at $V_G = 0.56$ V (charge state $N = +1$) recorded for different magnetic fields as measured with a lock-in technique (modulation amplitude 0.04 mV). Traces are offset by 2 $\mu$S for clarity. (b) Gray scale plot of $dI/dV$ versus $V$ and $B$ at $V_G = +0.56$ V. (c) Peak positions as a function of magnetic field taken from the data in (b) indicating a $g$ value of 2.56. (d) Same as (a) but at $V_G = -0.72$ V (charge state $N = +2$). Subsequent traces are offset by 1.2 $\mu$S. (e) $dI/dV$ traces at $V_G = -0.72$ V measured in a magnetic field of $B = 0$ T (gray) and $B = 9.2$ T (red). Arrows indicate the predicted positions of peaks at $B = 9.2$ T assuming the triplet splits according to $g_B B m_S$ with $g = 2$ and $m_S = -1, 0, 1$. (f) Gray scale plot of $dI^3/dV^3$ versus $V$ obtained by numerical differentiation of the measured $dI/dV$ at $V_G = -0.72$ V. The third derivative underlines the presence of three (two) peaks for negative (positive) bias voltage (peaks in the first derivative correspond to dips in the third derivative).

Figure 5. (a) Two orbitals, A and B, (depicted by the two boxes) are separated in energy by $\Delta$. $GS_{N=+1}$ and $ES_{N=+i}$ denote ground and excited states respectively for charge state $i = +1, +2, +3$ (excited states for $N = +3$ are not shown). $J$ is the interorbital, antiferromagnetic exchange energy, $E_C = e^2/2C$ is the electrostatic charging energy and $dU$ is the intraorbital Coulomb repulsion. At the bottom, $E_{add, N=+i}$ denotes the addition energies for charge state $i = +1$ and $+2$. (b) Schematic impression of the two-site orbital model for an OPV-5 molecule connected to gold electrodes on either side.

that are very similar to the singly charged state, as observed in the experiment.
We conclude with a few remarks on the generality and consistency of the results described in this letter. We have performed preliminary quantum chemistry calculations to account for the image charge effects. We find that the energy of the system crucially depends on the exact contact geometry which involves the Au–S bond angle and the distance to the image charge. In the experiment, we therefore expect a spread in the measured addition energies and charging energies in agreement with the observations. On the other hand, the exchange energy in this scenario is expected to be not very dependent on the exact contact geometry, since the distance between the two spins remains approximately the same. Measurements on the only other OPV-5 junction that displays higher-order processes are consistent with these observations. It also shows inelastic cotunnelling peaks at an energy of ±1.5 meV, close to the value reported here. This sample, however, exhibits higher addition energies, and as a consequence, only one degeneracy point could be resolved so that a further comparison with the model involving multiple charge states could not be performed.
