Abstract. Antarctic ice cores provide clear evidence of a close coupling between variations in Antarctic temperature and the atmospheric concentration of CO$_2$ during the glacial/interglacial cycles of at least the past 800-thousand years. Precise information on the relative timing of the temperature and CO$_2$ changes can assist in refining our understanding of the physical processes involved in this coupling. Here, we focus on the last deglaciation, 19 000 to 11 000 yr before present, during which CO$_2$ concentrations increased by $\sim$80 parts per million by volume and Antarctic temperature increased by $\sim$10°C. Utilising a recently developed proxy for regional Antarctic temperature, derived from five near-coastal ice cores and two ice core CO$_2$ records with high dating precision, we show that the increase in CO$_2$ likely lagged the increase in regional Antarctic temperature by less than 400 yr and that even a short lead of CO$_2$ over temperature cannot be excluded. This result, consistent for both CO$_2$ records, implies a faster coupling between temperature and CO$_2$ than previous estimates, which had permitted up to millennial-scale lags.

1 Introduction

The last deglaciation is the largest naturally-forced global climate change in Earth’s recent climate history. Its initial impetus, as with the sequence of glacial to interglacial transitions that came before it, is most commonly attributed to orbitally induced variations in insolation at high northern latitudes (Hays et al., 1976). Amplification through climate feedback processes of the relatively weak orbital signal is then required to explain the full magnitude of the glacial to interglacial climate change (Lorius et al., 1990). Changes in the carbon cycle play a central role among these feedbacks (Lorius et al., 1990; Shackleton, 2000; Shakun et al., 2012). Mounting evidence attributes a large component of the deglacial CO$_2$ increase to release of old CO$_2$ from the deep Southern Ocean through changes in its biogeochemistry and physical circulation (Anderson et al., 2009; Sigman et al., 2010; Skinner et al., 2010; Schmitt et al., 2012). However, there are open questions about the exact mechanisms involved and their relative contributions (Fischer et al., 2010; Sigman et al., 2010; Toggweiler and Lea, 2010). Determining the timing of the increase in atmospheric CO$_2$ with respect to the increase in temperature (hereafter “the lag”), is crucial for the models seeking to discriminate between mechanisms (Schmitz and Galbraith, 2008; Ganopolski and Roche, 2009; Lee et al., 2011).

Antarctic ice cores are unique in preserving a record of both temperature variation and atmospheric CO$_2$ concentration. Water stable isotope ratios ($\delta^{18}$O$_{\text{ice}}$ and $\delta$D$_{\text{ice}}$) from the ice are proxies for temperature above the inversion layer at the time of snow formation (Jouzel et al., 1997), while CO$_2$ is preserved in air bubbles in the ice. The transformation of snow to glacial ice isolates these bubbles at a depth of 50–100 m, leaving them younger than the surrounding ice by an amount $\Delta$age. The $\Delta$age must therefore be known for the lag between temperature and CO$_2$ to be accurately determined.

The most commonly cited studies constraining the CO$_2$ lag during deglaciation have used ice cores from the East...
Fig. 1. The phase relationship between regional Antarctic temperature and atmospheric CO$_2$. (A) Antarctic temperature proxy $T_{proxy}$ (green) and CO$_2$ data (1σ error bars) from Byrd (red) and Siple Dome (blue) on the GICC05 timescale. In the example shown, the CO$_2$ curves have been smoothed with a Gaussian filter of width 105 yr. (B) Lag histograms for the two lag determination techniques (direct correlation and correlation of derivatives) using each of the two CO$_2$ data sets (red, blue) and the best fit of Gaussian distributions (black curves and μ and σ values). The histogram widths reflect each lag determination’s sensitivity to the degree of data smoothing, CO$_2$ measurement uncertainties, and different choices of lag calculation data interval start and end points (black triangles in part (A)). The map shows the location of the Antarctic ice core sites mentioned in the text (source: NASA).
2 Materials and methods

2.1 Record synchronisation

The $T_{\text{proxy}}$ record is already available on GICC05, standardised to unit variance and zero mean (Pedro et al., 2011). We synchronise the timescales of the Siple Dome and Byrd CO$_2$ records to GICC05 using previously published gas–age depth ties from CH$_4$-based synchronisations of the Byrd (Blunier and Brook, 2001) and Siple Dome (Brook et al., 2005) records with Greenland records. The Byrd CO$_2$ data on the GRIP ss09 timescale (Johnsen et al., 1997) are transferred via GRIP depth (Blunier and Brook, 2001) to GICC05 ages by linear interpolation using stratigraphical markers (following Rasmussen et al., 2008, the markers are listed in their Table 2 and at http://www.iceandclimate.nbi.ku.dk/data/). Similarly, the Siple Dome CO$_2$ data on a GISP2 timescale (Ahn et al., 2004) are transferred via GISP2 depth (Meese et al., 1997) to GICC05 ages, again, by linear interpolation using stratigraphical markers (Rasmussen et al., 2008). The dating error introduced in the transfer from the GRIP ss09 and GISP2 time scales to the GICC05 timescale is negligible compared to Δage uncertainties and the uncertainties in the original methane synchronisations. All GICC05 dates mentioned in the text hereafter use the convention “ka1950” referring to thousands of years before 1950 AD.

2.2 Lag calculation

Visual inspection of the relative timing of the deglacial CO$_2$ and $T_{\text{proxy}}$ increase in Fig. 1a suggests little or no lag of CO$_2$ after temperature. We determine the lag quantitatively by maximising the time-lagged correlation between the deglacial temperature and CO$_2$ curves throughout the entire deglaciation. We consider this approach to be more robust than comparing dates of events (e.g. exclusively the start of the deglaciation) because its estimation is based on a much greater number of data points (see, e.g. Mudelsee, 2001). As a first approximation, setting aside Δage and CO$_2$ measurement uncertainties and prior to any smoothing/filtering of the data, the maximum of the time-lagged correlation suggests that CO$_2$ lagged temperature by one to two centuries for both CO$_2$ records. To refine this approximation and explore its sensitivity to various parameters, we apply a Monte Carlo-style sensitivity analysis.

Two methods of correlation are used for the sensitivity analysis: first, as above, by direct correlation between $T_{\text{proxy}}$ and CO$_2$ (“direct method”, similar to Siegenthaler et al., 2005); and second, by correlation between the corresponding derivative curves, $\partial T_{\text{proxy}}/\partial t$ and $\partial$CO$_2$/\partial t (“derivative method”, similar to Ahn et al., 2004). The derivative method has smaller sensitivity to misidentification of the pre- and post-transition levels at the expense of increased sensitivity to measurement noise, especially in the sections of sparse data. Since it is not clear a priori which approach is superior,
we apply both methods in parallel. Prior to the analyses, the CO$_2$ data are first linearly interpolated to 20-yr resolution over the 9–21 ka interval to match the 20-yr resolution of $T_{\text{proxy}}$. Derivatives, $\partial T_{\text{proxy}}/\partial t$ and $\partial$CO$_2$/\partial t, are calculated on the same grid. For both methods the data are then smoothed and the time-lagged correlation determined for lags in the $-400$ to $+1000$ yr range. The robustness of the lag calculation to CO$_2$ data uncertainty is evaluated by repeating the lag determination 100 times using random realisations of the CO$_2$ measurements, each sampled using the published uncertainties (represented by the error bars in Fig. 1a). As the lag shows some sensitivity to the degree of smoothing applied and the overall time interval chosen for assessment, we repeated the analysis using 19 different degrees of smoothing and 35 different choices of time interval. The different degrees of smoothing were applied by convolution with a Gaussian filter with a standard deviation ranging from 105–375 yr in steps of 15 yr; the minimum width of the smoothing corresponds to the approximate sampling rate of CO$_2$ data in the sparsely sampled parts of the data set, and the maximum was chosen to preserve a clear Antarctic Cold Reversal signature. Similar results were obtained by replacing the Gaussian filter with a simple running mean filter of equivalent half-width. The choices of the time interval start and end points for the lag calculation were varied within reasonable limits that encompass the overall deglaciation; specifically, the start and end ages were varied in 200 yr steps with the start spanning 19.4–18.2 ka b1950 (7 options) and end spanning 12.4–11.6 ka b1950 (5 options), as illustrated by the black triangles of Fig. 1a. This covers the start and end of the deglaciation as defined from the perspective of the onset and end of the warming trend in $T_{\text{proxy}}$ (Pedro et al., 2011), but excludes the early Holocene during which the correlation between Antarctic temperature and CO$_2$ appears to deteriorate (both CO$_2$ curves have high early Holocene values that have no counterpart in $T_{\text{proxy}}$). Given the close agreement between CO$_2$ and temperature throughout the deglacial warming and Antarctic Cold Reversal, the weaker relationship in the early Holocene may imply that different processes (e.g. processes operating outside the Southern Ocean) became more important in controlling atmospheric CO$_2$. A recently produced carbon-stable isotope record from the EDC core depicts a positive excursion in $\delta^{13}$C$_{\text{atm}}$ beginning around 12.2 ka, which the authors attribute to regrowth of the terrestrial biosphere (Schmitt et al., 2012).

A caveat associated with our lag determination method is that it implicitly assumes that the maximum of the lagged correlation does in reality provide a valid estimate of the lag. Simple linear models of this form are widely used in previous studies of temperature and CO$_2$ phasing (e.g. Ahn et al., 2004; Siegenthaler et al., 2005; Shakun et al., 2012); however, the result may somewhat change systematically if other models are used.

3 Results and discussion

Close correspondence between $T_{\text{proxy}}$ and both CO$_2$ records is observed (Fig. 1a), supporting the hypothesis that marine processes at high southern latitudes are linked to the deglacial CO$_2$ increase.

Quantitative results on the relative timing of the deglacial CO$_2$ and $T_{\text{proxy}}$ increase are summarised by the four histograms in Fig. 1b. Each distribution comprises 66,500 optimal lag values generated from the sensitivity analysis. The widths of the distributions thus reflect the sensitivity of the lag values to the lag determination method (direct or derivative), the CO$_2$ measurement uncertainties, differences between the two CO$_2$ data sets, smoothing filter widths and the start and end points used in the analysis. The distributions show larger spread for the derivative method, but overall consistency between the two CO$_2$ data sets and the two methods. Since the individual distributions are not completely independent, we take a conservative approach and pool all of the results. Applying a Gaussian best-fit to the pooled results suggests a mean ($\pm 1\sigma$) for the lag of 162 ± 89 yr.

We must also consider the relative dating uncertainty between $T_{\text{proxy}}$ and the two CO$_2$ records. This uncertainty comprises a component associated with synchronising CH$_4$ records between multiple cores (synchronisation error) and a component associated with the error of individual cores (error). The lag uncertainty in $T_{\text{proxy}}$ (relative to GICC05) ranges from 199–384 yr over the time interval considered, with a mean of 269 yr (Pedro et al., 2011). The relative dating uncertainty between $T_{\text{proxy}}$ and the two CO$_2$ records is smaller than the uncertainty in $T_{\text{proxy}}$, because the synchronisation error applies to both $T_{\text{proxy}}$ and the CO$_2$ data and thus partially cancels (as seen in the case where data from only one core is used and the synchronisation error cancels completely). Furthermore, the similarity of the results from the lag calculation using Siple Dome and Byrd CO$_2$ data supports that the records are well-synchronised on centennial scales or better. On this basis, we estimate an overall relative dating uncertainty (nominal $1\sigma$) of 200 yr. This term is independent of the 89-yr uncertainty captured by the sensitivity analysis. Taking the central estimate of the lag from the pooled sensitivity analysis and combining the two uncertainty terms in quadrature leads to a likely range for the CO$_2$ lag of $-56$ to 381 yr. From this we arrive at our main conclusion that the deglacial CO$_2$ increase likely lagged regional Antarctic temperature by less than 400 yr and that even a short lead of CO$_2$ over temperature cannot be excluded.

We conducted a series of jack-knife tests to assess the sensitivity of our lag estimate to the inclusion/exclusion of any of the individual stable isotope records used in $T_{\text{proxy}}$. By excluding in turn each one of the 5 records and using each of the two CO$_2$ data sets and correlation methods, the 20 histograms shown in Fig. 2 are produced. The mean lag value of these 1.33 million realisations is just one year larger than
the value obtained using all the records, but comprises some systematic differences. Excluding Law Dome, Byrd, Talos Dome or EDML records reduces the mean lag values by up to a couple of decades with a mean value of 12 yr, while there is somewhat larger sensitivity to exclusion of the Siple Dome record, which shifts the lag higher by on average 55 yr. A possible explanation for the somewhat larger sensitivity for Siple Dome may be an underestimate of $\Delta$age at that site, or the influence of local and/or non-climate signals. The abrupt increase in $\delta$D$_{ice}$ at around 15 ka in the Siple Dome record may be an example of such a local signal (as discussed previously, Severinghaus et al., 2003; Taylor et al., 2004). Note that an error in $\Delta$age would not affect the dating of the Siple Dome CO$_2$ record since it is not directly synchronised using methane records to Greenland.

Direct intercomparison of our result with prior estimates is complicated by the different time intervals considered and different ways to estimate uncertainties applied in the respective studies. Our result is in broad agreement with Ahn et al. (2004), which suggested short lag at Siple Dome, also determined over the entire deglaciation. As mentioned earlier, Fischer et al. (1999) were confident in a real lag between temperature and CO$_2$ for Vostok only at the start of the interglacials. There is a suggestion in both the Byrd and Siple Dome records of a larger lag at the onset of the Holocene (Fig. 1a), but this period is not included in the time window of our lag assessment as we assume it is likely influenced by processes acting on the carbon cycle outside the Southern Ocean. Monnin et al. (2001) defined the 800 ± 600 yr lag at EDC at the onset of deglaciation. The Byrd and Siple Dome CO$_2$ data is not sufficiently dense to constrain the lag at the same point, but our overall result is not inconsistent with the Monnin et al. (2001) estimate within its uncertainty range. Confidence in our result is provided by the sensitivity analysis and the consistent results for two different CO$_2$ records and two different correlation methods. The conclusion of Loulergue et al. (2007) that $\Delta$age (and thus the CO$_2$ temperature lag) was significantly overestimated during the deglacial onset by Monnin et al. (2001) also lends support to our result.

A brief comparison with the recent work by Shakun et al. (2012) is also warranted. Their study evaluates the phasing between the EDC CO$_2$ record and multi-proxy hemispheric and global (rather than exclusively Antarctic) temperature reconstructions. They report a CO$_2$ lag behind their Southern Hemisphere temperature reconstruction (620 ± 660 yr), a lead of CO$_2$ over their Northern Hemisphere reconstruction (720 ± 330 yr), and a short lead of CO$_2$ over their full global reconstruction (460 ± 340 yr). The southern lag and northern lead is attributed to an anti-phased hemispheric temperature response to ocean circulation changes (as also discussed further below) superimposed on globally in-phase warming driven by the CO$_2$ increase. This emphasises the role of CO$_2$ as both feedback and forcing in the deglacial warming. Within the quoted uncertainty bounds, the 620 ± 660 yr lag for the Southern Hemisphere is not inconsistent with our Antarctica-based result; also, considering the aforementioned $\Delta$age issues for EDC, their Southern Hemisphere lag is likely somewhat overestimated (and the northern and global lead are likely underestimated). The larger uncertainty range around the Shakun et al. (2012) result must be expected given the challenges of synchronising records from multiple proxy types. In our view, the remarkable similarity of the Antarctic temperature and CO$_2$ curves and the independent evidence that the high latitude Southern Ocean was a centre of action in the deglacial CO$_2$ release make the lag determination from an Antarctic perspective critical for constraining the mechanisms involved in the CO$_2$ increase.

Additional observational constraints on the processes involved in the CO$_2$ increase are obtained by considering in more detail the millennial and sub-millennial trends in CO$_2$ throughout the deglaciation. The CO$_2$ increase, as noted previously (Fischer et al., 1999; Monnin et al., 2001), occurs in two main steps. These steps coincide with the two periods of significant warming in $T_{proxy}$ (pink bands, Fig. 3) and are separated by a step down in CO$_2$ concentration as $T_{proxy}$

---

**Fig. 2.** Lag histograms for the two methods of determining the lag of atmospheric CO$_2$ after regional Antarctic temperature changes (direct correlation and correlation of derivatives), using each of the two CO$_2$ data sets (Byrd and Siple Dome). The gray background histograms are based on the complete $T_{proxy}$ composite, the same as in Fig. 1b. The superimposed curves show the corresponding lag histograms when excluding in turn each of the 5 records from the $T_{proxy}$ composite (jack-knifing): excluding Siple (red), excluding Law Dome (green), excluding Byrd (blue), excluding EDML (cyan), and excluding Talos Dome (magenta).
exhibits significant cooling within the core of the Antarctic Cold Reversal (dark blue band, Fig. 3).

Evidence from Southern Ocean marine sediment cores directly links each of the two warming steps with release of CO₂ accumulated in the deep Southern Ocean during the last glacial period: cores from south of the Antarctic Polar Front show pulses in upwelling (represented by opal fluxes) synchronous with each warming step (Anderson et al., 2009) and coincident with negative excursions in atmospheric δ¹³C (Schmitt et al., 2012), while cores from the Atlantic sector of the Southern Ocean identify a source of old (¹⁴C-depleted) carbon-rich deep water that dissipated over two corresponding intervals (Skinner et al., 2010). An explanation consistent with the near-synchronous temperature and CO₂ response identified here proposes that the increases in upwelling were responsible for the simultaneous delivery of both sequestered heat and CO₂ to the atmosphere around Antarctica (Anderson et al., 2009; Skinner et al., 2010). This does not imply that the Southern Ocean is the only important CO₂ source during deglaciation; in a coupled system it is plausible that other processes operating outside the region may also correlate with Antarctic temperature.

We now consider the time relationship between $T_{\text{proxy}}$ and the major millennial and sub-millennial climate events recorded by the North GRIP δ¹⁸O冰 record (Fig. 3); i.e. the timing of the well-known bipolar seesaw (Broecker, 1998; Stocker and Johnsen, 2003). Since $T_{\text{proxy}}$ and the CO₂ records are synchronised to GICC05, the records from both hemispheres can be directly compared. Fig. 3 reveals that there is also little or no time lag separating the major millennial and sub millennial climate transitions in Greenland (Lowe et al., 2008) from the onsets and ends of the warming and cooling trends in Antarctica (Pedro et al., 2011). A picture thus emerges from the ice cores of rapid (centennial-scale or faster) coupling between Antarctic temperatures, Greenland temperatures and atmospheric CO₂.

We give attention here to two potentially complimentary mechanisms which appear consistent with these observations. One mechanism supports a greater role for atmospheric pathways (Anderson et al., 2009; Toggweiler and Lea, 2010;
Lee et al. (2011) while the other supports a greater role for the ocean (Schmittner and Galbraith, 2008; Skinner et al., 2010). Neither mechanism directly specifies the proximal trigger of deglacial warming; indeed, this important point is not yet resolved. A possible forcing model suggests that orbitally-driven increases in boreal summer insolation during Greenland Stadial 2 initiate local warming and retreat of Northern Hemisphere ice sheets. Attendant freshwater release into the North Atlantic then weakens and displaces southward the Atlantic Meridional Overturning Circulation (AMOC) (Ganopolski and Rahmstorf, 2001; McManus et al., 2004). A feedback process has recently been proposed wherein the weakened overturning leads to a warming of North Atlantic subsurface waters (Marcott et al., 2011; Gutjahr and Lippold, 2011), destabilising ice shelves and in turn driving further ice and freshwater release (Álvarez-Solas et al., 2011). The atmospheric pathway proposes that surface cooling and sea ice expansion in the North Atlantic region initiates an atmospheric reorganisation in which both the Inter-Tropical Convergence Zone and the Southern Hemisphere mid-latitude westerlies are displaced south and/or intensified (Anderson et al., 2009; Toggweiler and Lea, 2010; Lee et al., 2011). The changed westerly regime over the Southern mid- and high-latitude oceans then displaces cold fresh surface waters, melts and dissipates sea ice, and draws up warmer deeper waters, which release heat and CO₂. A recent modeling study lends support to this hypothesis and also incorporates an important role for ocean biogeochemical feedbacks (Lee et al., 2011). In line with the constraints identified here, the model supports essentially simultaneous North Atlantic cooling and atmospheric CO₂ release from the high-latitude Southern Ocean, corresponding to an atmospheric CO₂ rise of 20–60 ppm where the range is dependent on the biological response. However, Lee et al. (2011) do not simulate the observed response of Antarctic temperatures, possibly due to fixed Southern Hemisphere sea ice.

The ocean pathway invokes the bipolar seesaw: weakening of the AMOC reduces northward ocean heat transport, thereby allowing heat to accumulate in the south (Broecker, 1998; Stocker and Johnsen, 2003). This melts back sea ice, removing a physical barrier to the release of CO₂ and exposing the Southern Ocean surface waters to the action of the westerlies. As above, the strengthened westerlies promote upwelling and ventilation of CO₂ from the deep waters (Skinner et al., 2010). The bipolar seesaw, as originally conceived (Broecker, 1998), operates on the millennial timescales of ocean heat transport and hence fails to meet the timing criteria identified here. However, an ocean wave-mediated seesaw (Stocker and Johnsen, 2003) could be capable of sufficiently rapid signal transmission. In one model study, the bipolar-seesaw changes in the circulation modes couple with changes in ocean biogeochemistry and carbon storage in the terrestrial biosphere to produce little or no lag between Greenland and Antarctic temperatures and CO₂ changes (Schmittner and Galbraith, 2008). Unlike Lee et al. (2011), this model does simulate the observed seesaw relationship between North Atlantic and Greenland temperatures. Notably, the initial (within the first 250 yr) rapid response in CO₂ in Schmittner and Galbraith (2008) is attributed to CO₂ release from the terrestrial biosphere (triggered by cooling associated with the AMOC reduction) and not to physical or biogeochemical components of the Southern Ocean carbon cycle. However, the response of terrestrial vegetation models and the interplay between ocean and vegetation responses is known to be highly model-dependent (Bouttes et al., 2012). Recent studies also emphasise the sensitivity of the timescales of ocean ventilation to model resolution; at least under modern boundary conditions, meso-scale eddy-resolving ocean models suggest much faster ventilation times than the coarser resolution models that are currently used for palaeo-simulations (Maltrud et al., 2010).

Current palaeo-modeling efforts appear to be accurately simulating key components of the deglacial sequence of events. However, there is not yet a simulation which fully captures all of the observed trends and phase relationships between Antarctic and North Atlantic temperatures and atmospheric CO₂. The results presented here, with their improved timing constraints over previous studies, provide a more stringent target for future modeling efforts.

4 Conclusions

The ice core observations point to a tightly-coupled system operating with little or no time delay between the onsets/terminations of North-Atlantic climate stages and near-simultaneous trend changes in both Antarctic temperature and atmospheric CO₂. As it stands, the observed timing of events lends support to the current concept of an atmospheric teleconnection between the northern and southern high-latitudes which forces wind-driven CO₂ release from the Southern Ocean. However, sorting out the relative roles of atmospheric and oceanic coupling mechanisms and the interactions between them remains a major challenge. More densely sampled and higher precision CO₂ measurements from high-accumulation ice core sites may assist with constraining the time evolution of the Antarctic temperature and CO₂ phasing during different stages of the deglaciation. Further progress in understanding these mechanisms requires more work at the interface between palaeoclimate observation and Earth system modeling; in particular, modeling efforts to more tightly constrain the potential timescales of bipolar-seesaw induced changes in CO₂ ventilation are needed.

The \( T_{proxy} \) series and CO₂ records on the GICC05 timescale are archived at the Australian Antarctic Data Center (http://data.aad.gov.au/) and at the World Data Center for Paleoclimatology (http://www.ncdc.noaa.gov/paleo/).
