Abstract

Amino acids can induce yeast cell adhesion but how amino acids are sensed and signal the modulation of the FLO adhesion genes is not clear. We discovered that the budding yeast \textit{Saccharomyces cerevisiae} CEN.PK evolved invasive growth ability under prolonged nitrogen limitation. Such invasive mutants were used to identify amino acid transporters as regulators of \textit{FLO11} and invasive growth. One invasive mutant had elevated levels of \textit{FLO11} mRNA and a Q320STOP mutation in the \textit{SFL1} gene that encodes a protein kinase A pathway regulated repressor of \textit{FLO11}. Glutamine-transporter genes \textit{DIP5} and \textit{GNP1} were essential for \textit{FLO11} expression, invasive growth and biofilm formation in this mutant. Invasive growth relied on known regulators of \textit{FLO11} and the \textit{Sfl1-Ptr3-Ssy5} complex that controls \textit{DIP5} and \textit{Gnp1}, suggesting that Dip5 and Gnp1 operate downstream of the \textit{Sfl1-Ptr3-Ssy5} complex for regulation of \textit{FLO11} expression in a protein kinase A dependent manner. The role of Dip5 and Gnp1 appears to be conserved in the \textit{S. cerevisiae} strain \textit{SFL1} since the dip5 gnp1 \textit{SFL1} mutant showed no invasive phenotype. Secondly, the amino acid transporter gene \textit{GAP1} was found to influence invasive growth through \textit{FLO11} as well as other \textit{FLO} genes. Cells carrying a dominant loss-of-function \textit{PTR3647::CWNKNPLSSIN} allele had increased transcription of the adhesion genes \textit{FLO1}, 5, 9, 10, 11 and the amino acid transporter gene \textit{GAP1}. Deletion of \textit{GAP1} caused loss of \textit{FLO11} expression and invasive growth. However, deletions of \textit{FLO11} and genes encoding components of the mitogen-activated protein kinase pathway or the protein kinase A pathway were not sufficient to abolish invasive growth, suggesting involvement of other \textit{FLO} genes and alternative pathways. Increased intracellular amino acid pools in the \textit{PTR3647::CWNKNPLSSIN}-containing strain opens the possibility that \textit{Gap1} regulates the \textit{FLO} genes through alteration of the amino acid pool sizes.

Introduction

Nitrogen is a vital metabolite in living organisms and nitrogen metabolism governs major developmental decisions in \textit{Saccharomyces cerevisiae}. For example, nitrogen starvation triggers diploid cells to undergo meiosis [1] and can lead to quiescence of both haploid and diploid cells [2]. Low concentrations of nitrogen induce pseudohyphal growth through elongated growth and polar budding [3] while propagation of haploid cells on rich complex medium leads to biofilm formation and invasive growth [4,5].

Biofilm, pseudohyphal growth and haploid invasive growth are dependent on the cell wall adhesin gene \textit{FLO11} (\textit{MUC1}), which confers cell-surface adhesion [6,7]. Cellular access to nitrogen is linked to \textit{FLO11} expression through the cyclic AMP-protein kinase A (cAMP-PKA) pathway and the general transcription factor Gen1 [8,9]. However, a central question is how the yeast cell senses extracellular nitrogen in the form of amino acids and the signal is transmitted to activation of \textit{FLO11}.

Nitrogen in the form of ammonium induces transcription of \textit{FLO11} via the high-affinity ammonium transporter Mep2 and several observations support the hypothesis that Mep2 is an ammonium receptor [8,10]. However, the ability to transport ammonium appears to be essential for the signaling function of Mep2 [11] suggesting that Mep2 is a transceptor or transports ammonium to an intracellular receptor. Mep2 is proposed to induce expression of \textit{FLO11} via the cAMP-PKA pathway, based on the findings that exogenous cAMP, dominant active \textit{RAS2} or \textit{GAP1} alleles are able to restore pseudohyphal differentiation in a \textit{Δmep2} strain [8].

Lorenz and Heitman observed that pseudohyphal growth on proline and glutamine-based medium was not dependent on \textit{MEP2} [8] and hypothesized that amino acid transporters could have a function similar to Mep2. In the current work we have
explicitly tested the role of amino acid transporters in the regulation of \textit{FLO11}, since these transporters have not yet been shown to play a role in biofilm formation, pseudohyphal or invasive growth.

Glutamine transport is mediated by Gnp1, Agp1, Gap1 and Dip5 [12–15] while proline is transported by Put4 and the general amino acid transporter Gap1 [16]. Transcription of \textit{GNP1}, \textit{AGP1} and \textit{DIP5} is induced by extracellular amino acids through the Ssy1-Ptr3-Ssy5 (SPS) complex and deletion of \textit{SSY1} leads to a 5–15 fold reduction in \textit{DIP5} and \textit{GNP1} expression [13,17,18]. Counter intuitively, deletion of \textit{SSY1} or \textit{PTR3} lead to increased invasive growth in the \textit{S1278b} strain background [17] while the opposite would be expected if invasive growth only depended on \textit{GNP1}, \textit{AGP1} or \textit{DIP5}. A cause of the invasive growth in the \textit{syl} and \textit{ptr3} mutants may be increased expression of \textit{GAPI} and higher levels of intracellular amino acids.

Here we investigated the importance of the amino acid transporters Gap1, Dip5 and Gap1 in regulation of \textit{FLO11}-dependent invasive growth. We hypothesize that (i) the general amino acid permease Gap1 is essential for invasive growth and \textit{FLO11} expression under conditions where \textit{GAPI} is highly expressed and (ii) that Gap1 and Dip5 are essential for \textit{FLO11} dependent invasive growth in conditions where \textit{GAPI} is not expressed.

**Results**

**Nitrogen-limited \textit{S. cerevisiae} Populations Evolve Invasive Growth**

To investigate the role of amino acids transporters for invasive growth and \textit{FLO11} regulation, we initially tested the phenotype of \textit{gap1}, \textit{dip5} and \textit{gap1} mutants in the \textit{S1278b} strain background but neither of these single gene deletions led to the loss of the invasive growth phenotype (Fig. S1). In an alternative approach we selected invasive mutants and used these as background for further analysis of amino acid regulation of \textit{FLO11}. Invasive mutants appeared in populations of the normally noninvasive \textit{S. cerevisiae} (CEN.PK113-7D) when propagated under nitrogen limitation (Fig. 1A–D). Clones were isolated from two haploid CEN.PK113-7D populations of 10^10 cells after 250 generations in continuous bioreactors, limited for ammonium or glutamine respectively.

**Clones \textit{Sfl1}^{Q320STOP} and \textit{Ptr3}^{647:C...N} Induce Invasive Growth**

To characterize clones from nitrogen-limited populations, we compared the genomes of six clones to the wildtype using DNA tiling arrays, revealing 12 to 88 single nucleotide polymorphisms (SNPs) per genome. We characterized the SNPs that affected ORFs by PCR and Sanger sequencing and verified up to two mutations in ORFs per clone (Table 1). Mutant alleles identified in the descendants were subsequently introduced into the wildtype strain to test if these caused the invasive growth phenotype. All gave rise to invasive phenotypes, except for a deletion of the general amino acid permease gene \textit{GAPI} (Fig. 2A–C).

We focused our work on two of the invasive clones from the glutamine-limited population. The clone \textit{Sfl1}^{Q320STOP} (Table 1) carries two mutant alleles: the nonsense mutation \textit{gfl1}^{Q320STOP} that leads to a truncation of \textit{Sfl1} at residue 320 and the \textit{pho90A2014G} mutation that substitutes threonine with alanine at residue 672 of Pho90. Clone \textit{Ptr3}^{647:C...N} (Table 1) carries a partial substitution of the \textit{PTR3} ORF with the long terminal repeat (LTR) of a Ty1 element from residue 1941 of \textit{PTR3}. This leads to substitution of the 31 C-terminal amino acids of \textit{Ptr3}, starting from residue 647, with 11 novel residues CWNKNPLSSIN encoded by the Ty1 element.

**\textit{GAPI} Transcription is Induced in \textit{Ptr3}^{647:C...N}**

\textit{Ptr3} is part of the SPS complex that responds to the presence of amino acids in the environment and induces transcription of amino acid transporter genes including \textit{AGP1}, \textit{GNP1} and \textit{DIP5} [13,17,18], which encode glutamine transporters. Transcript profiling of the \textit{Ptr3}^{647:C...N} clone revealed that \textit{DIP5} and other \textit{Ptr3}-regulated transporter genes (\textit{GNP1}, \textit{PTR2}, \textit{BAP2}, \textit{BAP3}, \textit{TAT1}) had strongly reduced mRNA levels relative to the wildtype (Fig. 2D). The general amino acid permease gene \textit{GAPI} on the other hand, had a 10-fold increase in transcription level. The \textit{Ptr3}^{647:C...N} clone also had increased transcript levels of \textit{FLO} genes, which are involved in cell-surface and cell-cell adhesion and could potentially explain the adhesive phenotype. \textit{FLO5} and \textit{FLO9} were mildly induced while \textit{FLO11} was upregulated 10-fold (Fig. 2D). Northern blot analysis showed that \textit{FLO11} had increased mRNA levels in the \textit{Ptr3}^{647:C...N} mutant showing that also \textit{FLO11} had been induced (Fig. 3B). We found a clear discrepancy between \textit{FLO11} mRNA levels found in the Northern blot and the array analysis (Fig. 2D). This difference could be caused by binding of unispecific mRNA species to the 60-mer probe used in the array analysis. The 621 bp long probe used for Northern blot analysis was more representative for the \textit{FLO11} mRNA levels.
GAP1 is Essential for FLO11 Expression and Invasive Growth in Ptr3647::CWN

To test if increased GAP1 expression was causative for FLO expression and invasive growth we deleted GAP1. The gap1Ptr3647::CWN mutant lost the ability to grow invasively while deletion of the glutamine transporter genes DIP5 or GNP1 in Ptr3647::CWN did not affect invasiveness (Fig. 3A). Northern blot analysis showed that FLO11 mRNA could not be detected in the gap1Ptr3647::CWN mutant (Fig. 3B), suggesting that GAP1 was essential for FLO11 expression and invasive growth in this mutant.

GAP1 also Induce Invasive Growth Independent of FLO11

We next tested if the regulation of invasive growth in the Ptr3647::CWN clone was dependent on FLO11 and known

![Figure 2. Mutant alleles restore invasive growth in wildtype strain and invasiveness correlates with increased FLO11 mRNA. Mutations from invasive descendants of glutamine- and ammonium-limited populations were reconstituted in the wildtype strain (A) and tested for invasive growth (B). Distribution of strains with pho9672A (RB389), sfl1D (RB567), PTR3647::CWN (RB567), gdh1D206E (RB484), gap1D (RB318) (C). mRNA levels for FLO adhesion genes (italic) and amino acid permease genes (italic bold) are shown for glutamine-limited mutants Ptr3647::CWN and Sfl1Q320STOP after growth to mid-exponential phase in liquid YPD (D). Presented are log2-transformed ratios of transcripts. The color code bar illustrates fold-change in mRNA in mutants relative to the wildtype strain CEN.PK113-7D. For the entire clustering of genes with more than 2-fold altered mRNA levels see Fig. S2. doi:10.1371/journal.pone.0041272.g002](http://www.plosone.org/figure2.1)
regulators of FLO11 [19]. Invasive growth was still maintained after gene-deletion of either FLO11, the mitogen-activated protein kinase (MAPK) transcription factor gene TEC1, or the PKA-pathway genes TPK2 and CYR1. The same result was obtained when we deleted the transcription factor genes GCN4 and MSS11 as well as the SPS-component gene SSY1 (Fig. 3C–E). Only deletion of the PTR3647::C…N allele with a ptr3::KanMX cassette led to loss of invasive growth. Hence, besides FLO11, a second response was responsible for invasive growth in Ptr3647::C…N. The response was dependent on high GAP1 expression and not dependent on the MAPK-, PKA- and SPS-pathways.

Intracellular Amino Acid Pools are Increased in PTR3647::C…N

To explain the role of Gap1 for invasive growth, we hypothesized that Gap1 could either i) change the balance in the intracellular pools of certain amino acids, ii) affect the activity of invasive growth regulators, and/or iii) act as receptors, eliciting a signal transduction pathway causing invasiveness. To test the first hypothesis, amino acid pool sizes were determined for clones Ptr3647::C…N and Sfl1 Q320STOP (Fig. 4A). Compared to the wildtype strain, glutamine pools were almost two-fold higher in the Ptr3647::C…N clone while the pool of the nitrogen-rich vacuolar amino acids lysine, histidine and arginine was as high as 2.5-fold higher than in the wildtype. We hypothesized that high levels of glutamine induced invasive growth. Both Ptr3647::C…N and Sfl1 Q320STOP were invasive when grown on medium with 100 mM glutamine as the only nitrogen source, while the wildtype strain remained noninvasive. The strains were not invasive on ammonium (Fig. 4B) suggesting that the effect was glutamine specific.

PTR3647::C…N is a Dominant Loss-of-function Allele

The transcript profile of Ptr3647::C…N was similar to transcript profiles of ptr3 deletion mutants, with severe reductions in transcript levels of SPS-regulated amino acid and peptide transporters GNP1, PTR2 and DIP5 (Fig. 2D; [17]). Hence, PTR3647::C…N behaves as a loss-of-function allele when expressed on YPD. Reconstitution of the PTR3647::C…N allele in the wildtype strain (Fig. 2A–C) and mating of the resultant invasive clone with a wildtype PTR3 strain, CEN.PK110-16D, revealed that the PTR3647::C…N allele was dominant for invasive growth (data not shown). Moreover, the finding that SSY1 deletion did not suppress the invasive phenotype of Ptr3647::C…N (Fig. 3C–E) suggested that the PTR3647::C…N allele is epistatic to ssy1 and supported that it is dominant. Taken together, these data suggest that the PTR3647::C…N allele must be a dominant loss-of-function allele.

GNP1 and DIP5 are Essential for FLO11 Expression and Invasive Growth in SFI1Q320STOP

The transcript profile of the invasive mutant SFI1Q320STOP revealed increased transcript levels of the adhesion genes FLO5, FLO9, FLO10 (Fig. 2D) and FLO11 (Fig. 5B). SFL1 encodes a
Amino Acid Transporters Regulate FLO11

PKA-regulated suppressor of FLO11 [20–22] and the sfl1Q320STOP mutation causes a truncation of the C-terminal part of Sfl1 that normally interacts with the co-suppressor Ssn6 [23]. Because the Ssn6–Sfl1 complex is essential for Sfl1-mediated FLO11 repression, the sfl1Q320STOP allele could be responsible for derepression of FLO11. The Sfl1Q320STOP clone also carried a SNP in the phosphate transporter gene PHO90 (Table 1), however the role of the pho90T672A allele in invasive growth regulation was unclear.

We next tested the role of glutamine transporter genes for invasive growth of Sfl1Q320STOP. Both a gnpl Sfl1Q320STOP mutant and a dip5 Sfl1Q320STOP mutant lost their adhesion properties (Fig. 5A) and Northern blot analysis supported these data, showing that FLO11 mRNA levels were reduced in these strains (Fig. 5B). Thus, GNP1 and DIP5 were essential for expression of FLO11 and invasive growth in a PKA pathway dependent manner. Deletion of GNP1 in the Sfl1Q320STOP strain had no effect on invasive growth and only led to a partial reduction of FLO11 expression (Fig. 5B), presumably because (i) GAPI was not highly expressed as in Ptr3647-..N and (ii) GNP1 and DIP5 were expressed and responsible for invasive growth.

We also found that GNP1 and DIP5 were essential for invasive growth in the S. cerevisiae strain S1278b. In S1278b, deletion of both GNP1 and DIP5 was required for loss of invasive growth (Fig. S1). Based on these results, the glutamine transporter genes appear to be a general requirement for invasive growth in the S. cerevisiae strains S1278b and CEN.PK.

Mutations in FLO11, MAPK, SPS and PKA Pathway Genes Suppress Sfl1Q320STOP Invasiveness

Expression of FLO11 in the Sfl1Q320STOP clone indicated that the FLO11 promoter was in a PKA pathway regulated derepressed state. Northern blot analysis revealed that FLO11 was in fact transcribed in the Sfl1Q320STOP clone and deletion of FLO11 showed that it was responsible for invasive growth (Fig. 5). The absence of Sfl1 repression is known to allow access of transcriptional activators to the FLO11 promoter [20–22]. Individual deletions of the genes TEC1, TPK2, CYR1, GCN4 and MSS11, which encode known regulators of FLO11 expression [17,19], led to the loss of invasive growth in all cases, except for the deletion of MSS11 (Fig. 5C–E). Hence, regulation of invasive growth in the Sfl1Q320STOP clone, CEN.PK background, was similar to regulation in S1278b. This result suggests that GNP1 and DIP5 induce FLO11 and invasive growth through identical pathways in the two strain backgrounds involving Gcn4, the MAPK- and PKA-pathways. We tested if regulators of GNP1 and DIP5 were also essential for invasive growth. Syr1-Ptr3-Syr5 induces the expression of GNP1 and DIP5 in response to amino acids [13,17]. We found that both PTR3 and SSY1 were essential for invasive growth in the Sfl1Q320STOP clone (Fig. 5), suggesting that the SPS complex regulates invasive growth through GNP1 and DIP5.

Amino acid pools in the Sfl1Q320STOP mutant and in the Sfl1Q320STOP dip5 mutant were almost identical to the wildtype strain with a slight increase in the glutamine pool. Thus, Sfl1 and Dip5 did not appear to influence invasive growth through pool sizes (Fig. 4A).

Dip5 Interacts with Gnp1 and Mep2

Interestingly, individual deletions of DIP5 and GNP1 resulted in complete loss of FLO11 expression and invasive growth in Sfl1Q320STOP (Fig. 5A). The finding that two amino acid transporter genes are essential for invasive growth under the same condition indicated corporate behavior between the transporters in the CEN.PK background. We tested the physical interaction between Dip5 and Gnp1, using the split-ubiquitin assay. In accordance with previous findings [24], we found that Dip5 interacts with itself (Fig. 6). Dip5 also interacted with the glutamine transporter Gnp1 and the ammonium permease Mep1 and Mep2 but did not interact with the glucose transporter Hxt1 (Fig. 6). Physical interaction between Dip5 and Gnp1 might cause a functional dependence for activity of both transporters and explain why deletion of either DIP5 or GNP1 led to complete loss of FLO11 expression in the CEN.PK background.
DIP5 is Essential for Biofilm Formation and Pseudohyphal Growth

Invasive growth shares many regulative constituents with biofilm and pseudohyphal growth [19]. We found that the Sfl1Q320STOP mutant formed biofilm on a polystyrene surface and that this was dependent on DIP5 and GNP1 (Fig. 7A). A diploid form of Sfl1Q320STOP, homozygous for the sfl1 mutation, formed pseudohyphal growth on synthetic low ammonium medium (SLAD); however, a sfl1Q320STOP/sfl1Q320STOP dip5/dip5 mutant lost the ability to form pseudohyphae (Fig. 7B). This showed that DIP5 was essential for the pseudohyphal phenotypes.

Discussion

The ammonium transporter Mep2 has been shown to be essential for expression of FLO11 and filamentous growth of S. cerevisiae under nitrogen limitation [8]. Our results suggest that amino acid transporters can have a similar function as Mep2, since they are essential for transcription of the cell surface glycoprotein gene FLO11, for biofilm as well as invasive growth in S. cerevisiae.

We show that GAP1 is essential for invasive growth and that invasiveness can be maintained even after deletion of FLO11. The highly expressed GAP1 phenotype correlates with an increased amino acid pool and an increased expression of FLO11 and other FLO genes. In cases where GAP1 is not expressed, we find that
GNP1 and DIP5 are essential for invasive growth and that they probably exhibit this role through PKA-pathway components and FLO11 expression.

GNP1 and DIP5 induction of FLO11 is likely to be dependent on an active PKA-pathway, since this regulation is observed in a Sfl1Q320STOP mutant. The transcription factor Sfl1 represses transcription of FLO11 when activity of the PKA pathway is low [20,22]. In a Sfl1Q320STOP background, Sfl1 is removed from the promoter when phosphorylated by an active PKA subunit, Tpk2, leading to FLO11 transcription [20–22]. The PKA pathway is partially inactive in the CEN.PK strain background due to a point mutation in the adenylate cyclase gene, cyr1K1876M [25]. Therefore, the wildtype CEN.PK strain is likely to have permanent low PKA activity that keeps the FLO11 promoter in the repressed state.

Mutant Sfl1Q320STOP lost the Sfl1 domain that interacts with the co-repressor Ssn6 [23] and the FLO11 promoter was likely converted to a state amenable to transcription similar to the state found when the PKA pathway is active.

Invasive growth of the Sfl1Q320STOP mutant appeared to be regulated by the same pathways described for the Sfl1Q320STOP background, including the essential constituents of the PKA-, MAPK- and general amino acid control (GCN) pathways (Fig. 5). Hence, GNP1 and DIP5 are likely to be involved in the regulation of one or more of these signaling pathways. The cAMP-PKA and MAPK pathways crosstalk and both are regulated by the G-protein, Ras2 [26] but how this complex signal network is wired in response to GNP1 and DIP5 could not be determined by conventional epistasis analysis.

The role of the SPS complex (Ptr3, Ssy1 and Ssy5) in regulating invasive growth is so far unclear [17]. Our results suggest that the SPS complex acts on FLO11 expression by inducing GNP1, DIP5 and potentially other amino acid transporter genes (Fig. 8A model). The model is supported by the fact that the function of GNP1 and DIP5 in FLO11 regulation appears to be conserved between CEN.PK and Sfl1Q320STOP (Fig. S1).

In the Ptr5Δ47-43C- strain, GAPI activity was essential for FLO11 expression (Fig. 5).
The phenotype of this strain appeared to be similar to previously reported recessive \textit{ptr3} and \textit{ssy1} mutants [17]. Ljungdahl and coworkers found that loss of Ptr3 activity leads to increased \textit{GAP1} transcript levels, reduced levels of \textit{GNP1} and \textit{PTR2} mRNA, invasive growth and increased pools of glutamate, glutamine, histidine, arginine and several other amino acids when grown on YPD [17]. However, in contrast to the recessive \textit{ptr3} alleles, the dominant loss-of-function \textit{PTR3647::C…N} allele complemented an \textit{ssy1} deletion, revealing that it was epistatic to \textit{SSY1} (Fig. 3C–E). We propose that \textit{Ptr3647::C…N} leads to an inactive SPS complex, under the tested conditions, causing reduced transcription of \textit{GNP1} and \textit{DIP5} (Fig. 8B model). \textit{GAP1} transcription is not under direct control of the SPS complex but might be induced in \textit{Ptr3647::C…N} as a result of altered activity of the TOR-regulated nitrogen catabolite repression pathway [27], giving rise to a higher intracellular amino acid pool. The glutamine transporter genes \textit{GNP1} and \textit{DIP5} are not essential for invasive growth in \textit{Ptr3647::C…N} probably because these genes have very low expression levels (Fig. 2D).

**Figure 8. Models of \textit{FLO} gene regulation by amino-acid transporters.** Extracellular amino acids induce the SPS complex at the plasma membrane (PM) and the activated complex elicits gene expression of amino acid transporters \textit{DIP5} and \textit{GNP1}. Dip5 and Gnp1 activate \textit{FLO11} transcription in a manner dependent on activity of the PKA-pathway (A). Inactive SPS signaling indirectly leads to increased transcript levels of \textit{GAP1}. Gap1 increases the amino acid pool concentration, which in turn triggers a PKA independent signal for induction of \textit{FLO} genes (B). PM, plasma membrane. NM, nuclear membrane. doi:10.1371/journal.pone.0041272.g008
In addition to Gap1’s role as an amino acid transporter, Gap1 has been reported to induce the PKA pathway, leading to rapid degradation of trehalose and glycogen in nitrogen-starved cells [28]. Hence, Gap1 could be acting on the FLO11 promoter via the PKA pathway. However, deletion of the PKA pathway genes CIR1 and TEP2 in Ptr3<sup>467-C…N</sup> were not sufficient for loss of invasive growth (Fig. 3C–E). Deletion of other regulatory factors essential for invasive growth in Δ<sup>1276b</sup> was also not sufficient to eliminate invasive growth by Ptr3<sup>467-C…N</sup>, suggesting a novel Gap1-dependent regulatory mechanism. This mechanism acts independent of the PKA-pathway and could regulate transcription of FLO genes other than FLO11 (Fig. 3B model). We found that deletion of FLO11 was not sufficient to abolish invasive growth, so alternative adhesion proteins must be involved. S. cerevisiae contains a number of FLO genes that confer cell-cell and cell-surface adhesion [29,30]. The FLO1, 5, 9 and 10 genes are normally inactive in laboratory strains though FLO1, FLO5 and FLO10 are known to have an impact on S. cerevisiae adhesion [29,31–33]. A likely candidate is FLO11, which was 10-fold induced in the Ptr<sup>467-C…N</sup> mutant relative to the wildtype and correlated with a high Gap1 and FLO11 expression (Fig. 2D).

In summary, our data demonstrate that amino acid transporters are involved in biofilm development and invasive growth. We propose that at least two modes of action exist on invasive growth: i) amino acid transporters operate downstream of pathway components, which in turn induce invasion of ∆<sup>1276b</sup> and ii) amino acid transporters or transceptors that directly activate a cytosolic signaling pathway linked to PKA-pathway components, which in turn induce FLO11. Our observations support that both permeases operate downstream of amino acid sensing complex, SPS, for regulation of FLO11. The latter, Gap1, may potentially induce invasive growth through increased amino acid pool levels that elicit a novel signal-cascade for gene expression of other FLO genes.

Materials and Methods

Strains

Strains used are listed in Table 2. The wildtype strain CEN.PK113-7D and the isogenic strains CEN.PK113-5D (ura2) and CEN.PK110-16D (tp1) were kind gifts from Peter Koetter, Frankfurt am Main, Germany. The two populations of CEN.PK113-7D and two populations of S288c evolved in glucose and glutamine limitation for 250 generations were isolated and three clones were chosen for analysis (Table 1). Descendants of CEN.PK113-7D were fed with modified minimal medium containing ammonium or glutamine at a concentration of 500 bp around the potential SNP and Sanger sequencing of these Ty1s. The PCR product revealed insertion of a long terminal repeat (LTR) identical to YMRCT7-1, YJRVT7-1 and YOLWTy1-1 (http://www.yeastgenome.org/), given that PTR3<sup>467-C…N</sup> had an insertion through transposition of one of these Ty1s.

The PTR3<sup>467-C…N</sup> allele was reconstituted into the wildtype strain background (CEN.PK113-5D isogenic to CEN.PK113-7D except for URA3) by transformation with a chimeric PTR3<sup>464-467</sup>:PTR3<sup>464-467</sup>-D PCR product, using the primers 5’-CATGATACCTTTGAG-GAG-3’ (identical to nucleotides 983–1001 of the PTR3 ORF) and 5’-tcgaatgtactggtttccgagcatgaattggcGATTCCATTTT-GAGAAGTCC-3’ (identical to nucleotides 215–234 of the Ty1 LTR and 213143–213173 of chromosome XI downstream of the stop codon of wild type PTR3). The PCR product was co-transformed into CEN.PK113-5D with a URA3 plasmid. A prototrophic transformant able to adhere and invade agar had the correct insertion of the PTR3<sup>467-C…N</sup> mutation, identified by PCR and Sanger sequencing. The resultant strain was named RB567.

Auxotrophic sfl1<sup>C958T</sup> and pho90<sup>A2014G</sup> were reconstituted into CEN.PK113-5D by co-transformation of a URA3 plasmid with PCR products carrying sfl1<sup>C958C</sup> or pho90<sup>A2014C</sup>. Correct clones were identified through prototrophic, invasive growth and Sanger sequencing and the resultant mutants denoted RB484 and RB389. sfl1<sup>C958T</sup> was not successfully introduced into CEN.PK113-5D; therefore a full sfl1 deletion was used as substitute (RB595). YKRC811-gap1<sup>-</sup>-YKRC812 mutants (RB318, RB351, RB347) were selected on D-histidine [36] and YKRC811-gap1<sup>-</sup>-YKRC812 deletions were confirmed by PCR as described [35].

Auxotrophic ura3<sup>SI1/0</sup> and ptr<sup>467-C…N</sup> strains were selected on medium with 5-FOA [37] and the genotype confirmed by complementation with URA3-based plasmids to generate strains RB20 and RB428. PCR-based gene deletions were made as described [38], using primers to the loxP::KanMX:loxp cassette in pUG6 with 5'-flanking sequences of the 40 bp immediately upstream and downstream of the targeted ORF. Deletion mutants were selected on YPD with 200 mg L<sup>-1</sup> geneticin. Correct insertion of the pUG6-based PCR fragment was confirmed by diagnostic PCR on genomic DNA from genetin-resistant clones using primers for the KanMX cassette and the promoter sequence of the targeted gene (see Table 2 for deletion strains).

A MATa sfl1<sup>Q208STOP</sup> tp1 strain (RB52) was obtained by mating a MATa sfl1<sup>Q208STOP</sup> pho90<sup>A2014G</sup> ura3 strain, RB20, and CEN.PK110-16D and sporulating the resultant diploid. Diploid homozygous mutants were obtained by crossing the haploid mutants RB20 (MATa sfl1<sup>Q208STOP</sup> pho90<sup>A2014G</sup> ura3) and RB52 (MATa sfl1<sup>Q208STOP</sup> tp1). Standard yeast genetics and molecular biology methods were used [37].

Chemostat Culture

CEN.PK113-7D MATa was grown in modified minimal medium at dilution rates of 0.20 h<sup>-1</sup> as described [39]. Cultures were fed with modified minimal medium containing ammonium (in duplicated culture experiments) or glutamine at a concentration corresponding to 6 mM nitrogen and 230 mM glucose (calculated on nitrogen and carbon atom bases, respectively), which ensured that growth was limited by nitrogen source with all other nutrients...

in excess. After steady state was reached, cellular dry weight, metabolite concentrations and gas profiles were monitored as described [39] every thirteenth generation. All parameters were constant throughout cultivation including biomass yield, glutamine limitation: 0.22±0.01 g dry weight/g glucose consumed and ammonium limitation: 0.22±0.01 and 0.21±0.01 g dry weight/g glucose consumed. Dry weight was determined in the efflux medium to test if cells accumulated because of flocculation in the bioreactor. Residual concentrations of glutamine were below detection level (<30 μM). In the ammonium-limited chemostat, the residual ammonium concentration was less than 50 μM throughout fermentation. Glucose and nitrogen consumption and metabolites (biomass, ethanol and glycerol) throughout chemostat cultivation showed no changes and the C:N ratio was thus constant over time.

Culture Media

Media for the chemostat cultivations was as described [39]. Standard yeast media, YPD and SC were as described [37]. All standard media were variations of synthetic dextrose medium with 1.7 g L⁻¹ yeast nitrogen base without amino acids and ammonium sulphate, 20 g L⁻¹ glucose, and 18 g L⁻¹ agar. Low ammonium SLAD contained 0.05 mM ammonium sulphate as sole nitrogen source, while synthetic glutamine dextrose medium was supplemented with 100 mM glutamine as the sole nitrogen source.

Gene Expression Analysis

Cells grown in liquid YPD were harvested in mid-exponential phase by addition of an equal volume crushed ice and centrifugation. RNA was prepared by acid phenol extraction and hybridized to Agilent 60-mer yeast ORF expression microarrays as described [40]. Data were acquired using the Agilent scanner and extracted with Agilent software using standard settings. Ratios of mRNA levels in the descendants to the progenitor were sorted using a 3-fold cutoﬀ (Fig. S2). The 106 resultant Log2 transformed transcript ratios were clustered by centered Pearson correlation. All raw microarray data are available from the Princeton Microarray Database [http://puma.princeton.edu].

Tiling Arrays and SNP Identification

Allumetrix Yeast Tiling arrays 1.0 were used. Total genomic DNA was hybridized to probes spaced every 5 bases and the data were analyzed as described [41,49].

Northern Blots

Northern blot analysis was performed with RNA from cells in YPD in mid-exponential phase. Total RNA was isolated using an acid-phenol extraction protocol [42] and 10 μg separated by electrophoresis, blotted and hybridized as described [43] with the following modifications: a probe was prepared from a PCR-ampliﬁed 621 bp FLO11 DNA fragment from the 5’-end of FLO11 (∼60% homologous to other regions in the S. cerevisiae genome). The probe was radioactively labeled with [32P]-CTP using a Prime-it II Random Primer Labeling Kit (Agilent Technologies, USA) and puriﬁed from unincorporated nucleotides using Illustra ProbeQuan G-50 Micro Columns (GE Healthcare, UK). The membrane was pre-hybridized with Ambion ULTRAhyb (Life Technologies Ltd., UK) for 2 hours at 42°C before addition of labeled probe. Intracellular Amino Acid Pools

Intracellular amino acids were extracted with trichloroacetic acid as described [44] and quantiﬁed by reverse-phase HPLC using an LKB-Alpha Plus amino-acid analyser [45].

Split-ubiquitin Interaction assay

The split-ubiquitin interaction assay was essentially as described [46]. S. cerevisiae genes were ampliﬁed from genomic DNA [S288c] using gene-speciﬁc primers acaagtttgtacaaaaaagcaggctctccaaccac- cATGTG19-27-5 ORF and tcgcccccaacaccaacctttgaaagcggg- taX19-27-3 strand ORF without stop. The DIP5 PCR product was cloned in vivo by homologous recombination in the THY.AP4 strain, carrying the plasmid pMetYCgate, to form the plasmid pMet-DIP5-Cgate. The THY.AP5 strain, carrying the plasmid pNXgate33-3HA, was transformed with PCR products of either HXT1, MEPI, MEP2, DIP5 or GNP1 to form strains with the plasmids pN-HXT1-gate33-3HA, pN-MEPI-gate33-3HA, pN-MEP2-gate33-3HA, pN-DIP5-gate33-3HA and pN-GNP1-gate33-3HA. THY.AP4 and THY.AP5 are CEN.PK derivatives and transformants of THY.AP4 were selected on SC-leucine and transformants of THY.AP5 were selected on SC-tryptophan. Plasmids were isolated and ampliﬁed in Escherichia coli by standard methods and DNA insertion conﬁrmed by PCR. Protein-protein interactions between DIP5, fused to the N-terminal half of ubiquitin (Dip5-CubPLV), and Hxt1, Mepl, Mep2, Dip5, or Gnp1, fused to the N-terminal half of ubiquitin (NubG-X), were determined by mating strain THY.AP4 (Dip5-CubPLV) to strain THY.AP5 (NubG-X). Diploids were selected on SC-leucine and -tryptophan and interaction between Dip5-CubPLV and each NubG-fusion was determined by growth after 3 days on reporter plates (SCg-500 μM methionine and without leucine, tryptophan, adenine and histidine).

Pseudohyphal Transition, Invasive Growth and Biofilm Formation

Pseudohyphal growth assays were as described [3] and performed using diploid mutants. Invasive and adhesive growth was tested by incubating haploid cells on solid medium at 30°C for 2 days. Plates were photographed and a gentle stream of water used to rinse non-invasive cells from the plate. Plates were dried for 30 minutes and photographed again. Biofilm formation in polystyrene 96-wells plates was tested as described [3]. Bioﬁlm formation assay was conducted with tcp1 auxotrophs (CEN.PK110-16D, RB52, RB157, RB196, RB209, 10560-2B; Table 2).

Supporting Information

Figure S1 Amino acid permeases are essential for invasive growth in S.11 Q230STOP, Prx3457::C…N and S1276b. The role of amino acid permeases on invasive growth was tested in several strains: a ura3 auxotroph version of the CEN.PK wildtype (CEN.PK113-5D), the mutants S11 Q230STOP ura3 (RB20) and Prx3457::C…N ura3 (RB429) and the S1276b strain (10560-2B). In the ura3 S11 Q230STOP background we deleted dip5 (RB317), gap1 (RB197) and gap1 (RB531). In the ura3 Prx3457::C…N background we deleted dip5 (RB468), gap1 (RB469) and gap1 (RB547). In the S1276b background, we tested invasive growth ability of dip5 (RB598), gap1 (RB599), gap1 (RB600) and gap1 dip5 (RB157). All strains were grown as dot spots on rich complex medium (YPD) for 1 day at 30°C (A) and flushed with water to expose invasive growth (B).

(TIF)

Figure S2 Microarray analysis of descendants after prolonged nitrogen limitation. Six single clones were collected after chemostat cultivation with a single limited nitrogen source of either glutamine or ammonium. All other nutrients were in excess. After growth to mid-exponential phase in liquid YPD, microarray analysis was performed. Gene expression data are shown for the glutamine-limited descendants S11 Q230STOP,
