### Abstract

Members of the conspicuous bone-eating genus, *Osedax*, are widely distributed on whale falls in the Pacific and Atlantic Oceans. These gutless annelids contain endosymbiotic heterotrophic bacteria in a branching root system embedded in the bones of vertebrates, whereas a trunk and anterior palps extend into the surrounding water. The unique life style within a bone environment is challenged by the high bacterial activity on, and within, the bone matrix possibly causing O₂ depletion, and build-up of potentially toxic sulphide. We measured the O₂ distribution around embedded *Osedax* and showed that the bone microenvironment is anoxic. Morphological studies showed that ventilation mechanisms in *Osedax* are restricted to the anterior palps, which are optimized for high O₂ uptake by possessing a large surface area, large surface to volume ratio, and short diffusion distances. The blood vascular system comprises large vessels in the trunk, which facilitate an ample supply of oxygenated blood from the anterior crown to a highly vascularised root structure. Respirometry studies of *O. mucofloris* showed a high O₂ consumption that exceeded the average O₂ consumption of a broad line of resting annelids without endosymbionts. We regard this combination of features of the respiratory system of *O. mucofloris* as an adaptation to their unique nutrition strategy with roots embedded in anoxic bones and elevated O₂ demand due to aerobic heterotrophic endosymbionts.

### Introduction

The unique bone-eating organism, *Osedax* (Siboglinidae, Annelida) was first described in 2004 from a whale fall located at 2891 m depth in Monterey Bay, Pacific Ocean [1]. Since its first discovery it has been found on multiple whale falls in the Pacific and Atlantic Oceans, artificially deployed cow bones [2] as well as on other vertebrate bones such as those of teleost [3]. There are five formally described species, with at least a further 12 species known from genetic evidence [4,5]. In addition, convincing fossil traces of *Osedax* have been found in Oligocene and Pliocene mammal bones [6,7].

Evidence suggests that *Osedax* females utilize the complex organic compounds of the bone through endosymbiotic aerobic heterotrophic bacteria (Oceanospirillales) located in bacteriocytes in a root system that is embedded in the bone matrix [8,9]. The O₂ microenvironment around the embedded root system of *Osedax* has not been studied, yet this knowledge is crucial for understanding the function of *Osedax* in its natural habitat. The O₂ supply within the bone matrix is presumably strongly diffusion limited, and with whale bone lipid content reaching 45% in Sciac whales (closely related to Minke whales) [10] the bone interior may become O₂ depleted due to high heterotrophic microbial activity, including sulphur-reducing bacterial processes that generate sulphide, further reducing O₂ below the bone surface. External O₂ supply to the roots of *Osedax* via the bone matrix is thus highly unlikely. Yet, symbiosis with detoxifying sulphide-oxidizing bacteria has so far not been proven, though *Osedax* has been observed along with sulphophilic species and mats of white *Beggiaota*-resembling bacteria (Figure 1) or bones exhibiting ferrous sulphide precipitation [11–14]. The highly folded epidermis of the root structure of *Osedax* ‘green palp’ has recently been shown to lack a cuticle and possess an extensive microwillous border [15], potentially facilitating the uptake of organic substrates, but also facilitating interaction with sulphide from the root surroundings. In the methane seep-dwelling vestimentiferan *Lamellibiocha* the sediment-embedded posterior body region (also called root) is actually the main source of hydrogen sulphide uptake, and is used for maintaining the chemosynthetically reducing endosymbionts [16,17]. Respiratory features in other siboglinids involve ciliary or...
The shallow water species *Oseadax mucosfloris* has been found at 30 m and 125 m water depth off the coast of Tjärnö, Sweden [12,13], and at 120 m depth in Bjørnafjord, Norway [24]. Currently these are the only records of *Oseadax* from the Atlantic, though other species are found in shallow waters in both the East and West Pacific [4,25]. The 125 m deep locality near Tjärnö is characterized by stable oceanic salinity (34–35‰), temperature (5–7°C) and dissolved O2 concentration ranging from 4.6 to 6.3 ml O2 l−1 [13].

In the present study we investigated whether *Oseadax mucosfloris* is exposed to an inhospitable hypoxic or anoxic microenvironment by measuring the O2 distribution surrounding the embedded root system. We assessed possible morphological and/or physiological adaptations to the environmental conditions through detailed morphological studies of the respiratory surfaces and the blood vascular system as well as respiratory measurements of O2 consumption. The results are discussed in relation to the unique environment, endosymbionts, and embedded root structure of *Oseadax* as well as compared with studies of related annelids.

**Results**

**Ventilating mechanisms**

**Ciliary bands and sensory structures (anti acetylated α-tubulin staining and histology).** In the description below, we use a dorsal-ventral definition opposite to the one used by Rouse et al. [1,21], based on a new interpretation (Rouse & Worsaae, unpublished).

We found two previously unreported broad longitudinal ciliary bands dorso-laterally on each side of the oviduct on the anterior part of the trunk (Figure 2A, B, E). The ciliary bundles of the bands consist of multi ciliated cells, appearing pillow-like with numerous, conspicuously short cilia (<10 μm long) projecting outwards from the centre of the elliptical bundles (Figure 2C). The bundles are organized in an anterior-dorsal diagonal pattern within the longitudinal bands (Figure 2B). The ciliary bands narrow toward the posterior part of the trunk and are replaced by single tufts of cilia scattered basally across the trunk surface (Figure 2A). The short cilia appeared immotile, and with several longitudinal nerves running beneath, (Worsaae & Rouse, unpublished) their function may be sensory rather than ventilatory.

Two dense ciliary bands are found on each palp along their epidermal longitudinal lobes on each lateral side, as previously reported [12] (Figures 3A, B, E, 4C, 5A, F, G). The bands consist of multi ciliated cells with 70–90 μm long cilia (Figure 3E). The ciliary bands extend from near the basal part of the palps to the distal tip, beating in metachronal waves.

Two nerves, originating at the anterior part of the brain, innervate each palp. One nerve runs abfrontally, between the two lateral ciliary bands and the other nerve runs laterally underneath one of the ciliary bands (Figure 5A). Further details on the female *Oseadax* nervous system will be described elsewhere (Worsaae & Rouse, unpublished).

Pinnules (up to 100 μm wide) project perpendicularly from the frontal palp surface between the lateral ciliary bands, with a density of approximately eight pinnules across the palp per 50 μm palp length (Figures 3A, 5F, G). At the proximal end of the palps, pinnules are less developed than at the distal end, seemingly growing in length (up to 170 μm) synchronously with the growth of the palp (Figure 3A). A sensory cell extends through the centre of the pinnule with a distal perikaryon and a few external, presumably sensory, cilia (Figure 4G, D). Its axon seems to connect with one of the two major longitudinal palp nerves, possibly the

doi:10.1371/journal.pone.0035975.g002
Musculature (F-actin, phalloidin staining). The longitudinal muscles run along the entire length of the trunk (Figure 2A), originating posteriorly at the trunk basis, and inserting anteriorly at the base of the four palps (Figure 3D). In one individual, it was possible to detect clustering of longitudinal muscles into 14–16 bundles of >20 muscle strands in the posterior part of the trunk, anterior to the root structure (Figure 4A). Along, and around the entire trunk, the muscles are distributed in a dense cylindrical formation with an average of six strands per 50 μm (Figures 2D, E, 3D). The musculature is slightly separated internally to the oviduct (possibly by the nerve cords), as well as randomly along the trunk, creating minor gaps most likely for mucus gland exits or nerves (Figures 2A, 3D). Anteriorly, a gap in the musculature is found ventrally at the position of the brain, as well as at each of the four insertion points of the palps. At each of these four points, the longitudinal musculature divides into two bundles (of each 20–30 strands), encircling the insertion point of the palp (Figure 3D). The longitudinal palp muscles originate at the base and run along the entire length of the palps to their tips, separated by a smaller frontal and a larger abfrontal gap (Figures 3C, D, 5A). No longitudinal musculature was detected in the pinnules.

Around the ovisac and anterior root structure the longitudinal musculature divides, and together with the circular muscles, creates a mesh-like structure (Figure 4A). The musculature extends posteriorly along the roots in a cylindrical formation, supporting the tissue penetrating the bone.

Thin circular muscles are found peripheral to the longitudinal muscles along the entire trunk, with 24 strands per 50 μm (Figure 2D, E, 3D). The musculature is slightly separated internally to the oviduct (possibly by the nerve cords), as well as randomly along the trunk, creating minor gaps most likely for mucus gland exits or nerves (Figures 2A, 3D). Anteriorly, a gap in the musculature is found ventrally at the position of the brain, as well as at each of the four insertion points of the palps. At each of these four points, the longitudinal musculature divides into two bundles (of each 20–30 strands), encircling the insertion point of the palp (Figure 3D). The longitudinal palp muscles originate at the base and run along the entire length of the palps to their tips, separated by a smaller frontal and a larger abfrontal gap (Figures 3C, D, 5A). No longitudinal musculature was detected in the pinnules.

Around the ovisac and anterior root structure the longitudinal musculature divides, and together with the circular muscles, creates a mesh-like structure (Figure 4A). The musculature extends posteriorly along the roots in a cylindrical formation, supporting the tissue penetrating the bone.
apart (35–70 μm) in the posterior end than along the rest of the trunk (5–10 μm).

The circular musculature of the palps encircles the longitudinal musculature as a cylinder, with 18 muscle strands per 50 μm and is evenly distributed along the entire palp (Figure 3C). Fine circular muscles enclose each vessel of the pinnular loop (Figure 4C, D); they were likewise visible in the semi-thin sections on the outside of the pinnular loop and along the midline of each pinnule (Figure 5F, arrow tips), with a spacing corresponding to those shown with phalloidin staining (Figure 4C, D).

Blood vascular system

The trunk of Osedax mucofloris encloses two major longitudinal blood vessels (Figures 2E, 6A, B). The dorsal vessel is highly muscularized with circular musculature throughout its length (Figure 2D, E). No lateral connecting vessels between the major longitudinal vessels or epidermal capillaries were found in the trunk. From the trunk, the two blood vessels continue posteriorly into the root structure and increase in diameter (Figure 6A, B). When studied under the light microscope, the muscularized dorsal vessel is visible as a defined tube along the trunk, and continues into the anterior root structure, curling up in the centre anterior to the ovisac. The curling configuration is most likely caused by contraction of the basal part of the trunk. The exact further path of the vessel was difficult to determine. The Confocal Laser Scanning Microscope (CLSM) studies also showed the continuation of the dorsal blood vessel around the ovisac, revealing cylindrical musculature at the ovisac, corresponding in diameter to the musculature of the dorsal blood vessel of the trunk (Figure 4B).

The ventral blood vessel also continues into the root structure, but as a narrower and less defined vessel, the path of which was even more difficult to determine, than that of the dorsal vessel. Blood vessels of different sizes, as well as multiple obvious capillaries within the root tissue were observed (Figure 6B–E). Larger vessels extend out from the area of the ovisac and divide into thinner vessels (diameter: 7–30 μm). Capillaries were detected in the periphery of the root tissue (Figure 6E), with distances between the detected capillaries ranging from 65–220 μm.

Anteriorly, each palp encloses a pair of blood vessels created by invaginations of the inner lamina of the basement membrane of the epidermis (Figures 5F, G, 7C). Imaging of live specimens

doi:10.1371/journal.pone.0035975.g004
confirmed the presence of two blood vessels, running along the entire length of the palps.

The pinnules are largely filled by a blood cavity lined with a membrane, which fuses in between the two blood cavities along most of the pinnule length, thereby creating the pinnular loop (Figures 5B–G, 7C). The palps of the histological sections were 300 μm in diameter at the base and the palp epidermis was 50–75 μm thick. The palp diameter and the thickness of the
epidermis were both found to decrease towards the distal end of the palp.

Pinnules vary in diameter along their length and along the palp, with a median diameter of 30–40 μm for the pinnules and 20–40 μm for each blood vessel. The diffusion distance across the pinnule epithelium was measured on the semi-thin sections to be 1–2 μm, and for the epidermis of the distal part of the palps, the diffusion distance was measured to be ~30 μm.

Oxygen consumption

When corrected for background respiration, the measured O₂ consumption (MO₂) of O. mucosufloris ranged almost across a factor of ten from 220±93 μg O₂ g⁻¹ h⁻¹ to 2053±1950 μg O₂ g⁻¹ h⁻¹ (Table 1), depending on the approach used for measurement. MO₂ measured on O. mucosufloris inhabiting sectioned bone pieces (B1–B3) vs. MO₂ measured O. mucosufloris inhabiting bones in cuvettes (C1, C2), resulted in two distinctly different ranges of MO₂. The MO₂ of C1 and C2 was 220±93 μg O₂ g⁻¹ h⁻¹ and 238±29 μg O₂ g⁻¹ h⁻¹, respectively, while the MO₂ of B1–B3 range from 976±201 μg O₂ g⁻¹ h⁻¹ to 2053±1950 μg O₂ g⁻¹ h⁻¹. Methods and ranges are commented further in the discussion.

Oxygen levels around Osedax

Micro sensor measurements of O₂ concentrations in proximity to the bone interface were conducted, through agar-filled holes, on Osedax-colonized bone fragments in cuvettes. The obtained profiles of O₂ concentration in proximity to the bone interface showed steep O₂ gradients towards both the bone and tissue surface (Figure 8A, B). Anoxic conditions or very low O₂ levels were found at the bone surface, within the bone, and in proximity to the embedded root tissue of O. mucosufloris (Table 2). The average
Osedax mucofloris extend its palps and pinnules, with large respiratory surfaces, into the overlying O₂-rich water in order to uptake O₂. O₂ distribution to the root system is crucial as local uptake is not possible in the anoxic bone environment. The anoxic environment is partly produced by intense bacterial processes (green arrows) utilizing O₂ at the bone surface. Hydrogen sulphide is produced by anoxic bacterial processes within the bone matrix during decomposition of organic content using sulphate. Ventilation and branchial structures (palps) into the aerated water in order to facilitate ventilation or local O₂ supply to the epidermis, nor dense capillaries beneath the epidermis. Therefore, the epidermis of the embedded root structure is unlikely to facilitate ventilation or local O₂ supply to the Osedax root system. The O₂ necessary to maintain the metabolism and heterotrophic endosymbionts of the roots may instead primarily be transported via the blood vascular system to the chemoautotrophic endosymbionts in the trophosome [16,17,28].

Our study demonstrates the respiratory challenges faced by Osedax, as no oxygen was measured in the bone matrix as well as in the immediate vicinity of root structures and ovisac. Furthermore, we found no ventilating structures such as ciliary bands on the root epidermis, nor dense capillaries beneath the epidermis. Therefore, the epidermis of the embedded root structure is unlikely to facilitate ventilation or local O₂ supply to the Osedax root system. The O₂ necessary to maintain the metabolism and heterotrophic endosymbionts of the roots may instead primarily be transported via the blood vascular system from uptake at the aerated palps (Figure 7A). However, the microvillar root epidermis in Osedax does constitute a large surface area to volume ratio, which besides uptake of organic compounds may also facilitate uptake of e.g., hydrogen sulphide in the bone matrix. This is the case for the ‘root’ surface of the vestimentiferan Lamellibrachia, where hydrogen sulphide is absorbed and then transported via the circulatory system to the chemoautotrophic endosymbionts in the trophosome [16,17,28].

Previous studies of other close relatives of Osedax such as Vestimentifera and Sabellidae have shown anterior branchial structures to be of vital importance when tube-bound tissue is not site for O₂ uptake (Figure 7A–C). Uptake of O₂ over the trunk surface is possible, but a thicker epidermis, short and seemingly immotile ciliary bands and no obvious respiratory structures suggest that the trunk is a minor site of O₂ uptake. Oxygen does, to some extent, diffuse from the surrounding water into the mucus tube, thereby supplying the dwarf males.

The well-developed longitudinal musculature of the trunk serves to retract the trunk and palps into the tube and bone, presumably as protection from predators. As no regular retraction patterns of trunk musculature were detected, retraction into the tube is not considered a significant mode of ventilation for required O₂. Furthermore, the tube only surrounds the trunk, tightly fitting to the base of the trunk and the surface of the bone, preventing any water exchange to the ovisac and roots from the bone surface. The longitudinal musculature is moreover able to stretch the extensive branchial structures (palps) into the aerated water in order to increase the O₂ uptake.

The circular trunk musculature in O. mucofloris is weakly developed, as found in several other annelids [26,27]. The diagonal musculature revealed in the present study, may compensate for the weak circular musculature by having a similar supportive function. Diagonal musculature has most likely been mistaken for circular musculature in several annelids [26,27], including previous studies of Osedax [15,21].

MO₂ was determined in sea water at 100% atmospheric saturation and carried out on O. mucofloris inhabiting sectioned cow bone (B1–B3) and cow bone in cuvettes (C1–C2). *Standard deviation. *Numbers of measuring sequences on which MO₂ is based. doi:10.1371/journal.pone.0035975.t001

Discussion

Ventilation and branchial structures

The presence of highly vasculated palps and pinnules, the former densely ciliated showed that the anterior crown is the main...
Likewise, the anterior branchial structures of *O. mucofloris* seem morphologically adapted to facilitate efficient O₂ uptake from the surrounding water. As with the branchial plume of Vestimentifera [31,32], the anterior palps and pinnules of *O. mucofloris* have a large surface area to volume ratio and short diffusion distances. Furthermore, O₂ uptake is optimized by the two ventilating ciliary bands on each palp, a feature also seen in other Siboglinidae and in Sabellida in general [20,31,33].

A rough estimate was made of the surface area of the anterior crown, calculated from palp length given by Glover et al. [12], and the dimensions of palps and pinnules of *O. mucofloris* found in the present study. This results in a weight specific branchial surface area (SBSA) of ~22 cm² g⁻¹ fixed mass, which is similar to the SBSA of *Riftia pachyptila* and higher than the SBSA of fish, crabs and other annelids [31]. This is especially obvious when compared to the SBSA of e.g., *Arenicola marina* (4.00 cm² g⁻¹) [34], although this species can also take up O₂ across its general epidermis.

The estimated diffusion distance in *O. mucofloris* (pinnule epidermis 1–2 μm, palp epidermis ~30 μm) is furthermore comparable to what has been found for *R. pachyptila* (pinnules ~2.00 μm; branchial filaments ~25 μm) and *Ridgeia piscesae* (pinnules ~1.00 μm; branchial filaments ~17 μm) [31,32].

Interestingly, the present study showed that each pinnule is equipped with a distal sensory cell and external sensory cilia. These structures may sense disturbance in the water to avoid predators, as *Osedax* need not sense food items or reproductive indicators in the water [1,8,35]. Additionally, sensing of currents may also be beneficial in order to orientate the palps e.g., for optimal uptake of dissolved O₂. *Riftia pachyptila* does not have sensory structures on the pinnules, but does have long, separate sensory filaments that lack ciliary bands and pinnules. These structures, with unknown function, are placed between pinnulated filaments [33].
Blood vascular system

The quantity and complexity of capillaries in the root structure of *O. mucosiforis* reflects the high O2 demand of *Oseadox*, presumably for the metabolism of its heterotrophic endosymbionts and production and development of eggs. Similar capillaries are visible on the exposed ovisac of *O. frankpressi* (figure 2F in [1]) and *O. roseus* (figure 4E in [21]), while the present study shows the presence of capillaries supplying the more distally placed root tissue and bacteriocytes. However, the extent of capillaries does not match the extensive capillary network of the trophosome in other Siboglinidae [20,33]. This is in accordance with the original description [1] mentioning the lack of a discrete trophosome, the *Oseadox* trophosome instead being diffuse and beneath the epidermis of the embedded tissue.

The present study supports the basic histological findings with regard to the circulatory system of the palps in *O. roseus* [21]. The increased level of detail in the present study suggests similarities with some previous siboglinid studies [31,32,36]. The pinnular loop is most likely lined by an extension of the outer lamella of the basement membrane, which is in accordance with the findings of Norrevang [36]. No indication of a capillary plexus between the two elements of the loop was observed, as otherwise seen in *Riftia pachyptila* and *Ridgeia pisseae* [31–33]. In accordance with Norrevang’s [36] observations of blood flow in *Siboglinum*, the blood of *Oseadox* flows through an afferent vessel into the palp, through the pinnular loops and back through an efferent palp vessel (Figures 7B–C). This circulatory system carries oxygenated blood to the trunk and root system. In the present study of *O. mucosiforis* and previous studies of *Oseadox* [1,21] the main trunk blood vessel has been shown to be muscularized, and is now regarded as dorsal (Rouse & Worsaae, unpublished). This is in accordance with other annelids [37] and siboglinids [20,33], where the muscularized dorsal vessel, possibly assisted by a heart, creates blood flow in an anterior direction in the dorsal trunk vessel and posterior in the ventral trunk vessel. Rouse et al. [1] reported an anterior lying dorsal heart in the original description of the genus, not noted in any descriptions since and would now appear to be an error (Rouse, pers. obs.).

The main blood flow within the palp vessels may be generated by the circular body wall musculature of the palp. However, the thin circular musculature of the pinnules surrounding each branch of the looped blood vessel (Figure 4C, D) most likely assists local blood flow, as suggested for the tentacular vessels of *Riftia pachyptila* [22]. Musculature in anterior appendages has been found in several Vestimentifera, in the form of sphincter muscles located in the branchial lamella and filament vessels [31].

As with the trunk of *O. mucosiforis*, the anterior vestimentum of Vestimentifera lacks branching vessels between the ventral and the muscularized dorsal vessel [33]. The resemblance between the blood vascular systems adds new evidence to the hypothesis that the trunk of *Oseadox* and the vestimentum of Vestimentifera are homologous regions [21].

**Oxygen consumption**

The present study shows that *Oseadox mucosiforis* has a higher weight specific O2 consumption (MO2) than other resting annelids (Figure 9) [18]. This may reflect an elevated demand of the embedded tissue due to presence of heterotrophic aerobic endosymbionts, which have a higher metabolism than regular tissue. The measured MO2 actually corresponds to that found for *Riftia pachyptila* [22,23] (Figure 9), possessing a vast amount of chemosynthetic bacteria in their trophosome. Furthermore, a high MO2 may also reflect oxidative sulphide detoxification. The high MO2 corresponds well with the large SBSA and elaborate branchial structures, which are both usually associated with animals exhibiting a high O2 demand. This correlation is also found in *Artemia marina* with smaller SBSA and lower MO2 (red square, Figure 9).

Our data show that *O. mucosiforis* inhabiting bone in cuvettes (purple and yellow dots, Figure 9) have a lower MO2 than *O. mucosiforis* inhabiting sectioned cow bone (green, blue, red dots, Figure 9). Along with high standard deviations, this highlights the difficulties of measuring O2 consumption on these embedded worms. The variations are most likely caused by the difference in blind respiration measurements and the large biological activity present on decaying bone, which was difficult to quantify. Future studies should thus be carried out to more precisely determine the

**Table 3**

The Respiratory System of *Oseadox mucosiforis*.
from Cammen [18], the regression line (log $R = -1.682 + 0.850 \times \log W$) calculated from measurements of resting nonventilating annelids only. Dots: B1 (red), B2 (blue), B3 (green), C1 (purple), C2 (yellow). Triangles: Previous measured O$_2$ consumption of $R$. pachyptila. No sulphide present in water when measuring: Red, blue [22] and green [23]; sulphide present in water during measurement: Purple [23]. Red Square: O$_2$ consumption of resting Arenicola marina [52].

MO$_2$ of $O$. mucosus and the contribution of other O$_2$-consuming surfaces.

Osedax adaptations to the bone environment

The bone matrix exhibited strong O$_2$ depletion with anoxic or low O$_2$ levels at its surface and with areal O$_2$ consumption rates comparable to in situ diffusive O$_2$ uptakes measured in sediments proximate to whale falls [38]. The respiratory and circulatory system of Osedax is well suited to these environmental challenges. The elaborate branchial structures of the palp and pinnules of Osedax mucosus facilitate a high O$_2$ uptake from the surrounding seawater that, in combination with the blood vascular system, apparently enables sufficient oxygenation of the embedded tissue and endosymbionts. A similar, well-developed respiratory system is also found in other siboglinids (including Lamellibrachia) is highly efficient in hydrogen sulphide uptake [17]. Since the main trophic source of Osedax compared to other siboglinids (including Lamellibrachia) seems to be heterotrophic bacteria rather than sulphide-detoxifying chemoautotrophic bacteria [6], Osedax may instead possess physiological adaptations to detoxify sulphide.

Though beyond the scope of the present paper, microanalytical approaches such as microsensors [40,41] and functional imaging techniques [42] could yield a more complete mapping of the chemical microenvironment of Osedax, including the exact levels of sulphide exposure and spatio-temporal dynamics of O$_2$ in the root system. It would also be interesting to know whether Osedax have sulphide-binding properties of their haemoglobin as found in Vestimentifera [43,44], as they might use them to transport toxic sulphides from the area surrounding the root structure to e.g., the palps, somehow releasing the toxic compounds to oxygenated seawater or detoxifying them.

Materials and Methods

Sampling and aquarium setup

In January 2009, 3 replicate experimental sampling devices, using cow and whale bone, for recruitment of female Osedax (Figure 10) were placed at 125 m depth off the coast of Tjärnö, Sweden (58°52.976N; 11°05.715E) in close vicinity to a minke whale carcass sunk in October 2003 [13]. One device for morphological and reproductive studies was successfully retrieved in May 2009. A second device was retrieved in November 2009 for in vitro studies (respirometry and microsensor analysis) and additional morphological studies. Additionally, a piece of cetacean

doi:10.1371/journal.pone.0035975.g010
bone deposited at 123 m in the same area in May 2008 was retrieved in January 2009 and used for preliminary investigations and for designing experimental setups. In January 2009, the bottom water had a salinity of 34.6%, a temperature of 8.4 °C, and an O2 content of 78.7% atmospheric saturation.

Placement and retrieval were carried out with a remotely operated vehicle (ROV, Sperre Subhunting, Norway) operated from the R/V *Lophelia* (Sven Lovén Centre for Marine Science, University of Gothenburg, Sweden). Upon retrieval, the sampling device was placed in a cooling box with ambient aerated water and transported to the Marine Biological Section, University of Copenhagen within 8 hours. In the laboratory bones were kept in aerated seawater under *in situ* conditions, in aquaria (Vol 60 litre) with aeration, protein skinners and a recirculating pumping system. The *Oseax* “yellow-collar” shown as comparison in Figure 4 was sampled in November 2009 in Monterey Bay, California at 385 m from a Grey whale skeleton and stained in accordance to the protocol described below. All necessary permits were obtained for the described whale fall experiment; received from Karin Pettersson at the County Administrative Board Vastra Gotalands Lan, Oct. 2003. The field studies did not involve endangered or protected species.

**Fixation**

Specimens were carefully dissected from the bone and fixed for immunohistochemistry, benzidine staining and histology. Prior to dissection, *Oseax mucosparis* were anesthetized for 5–10 minutes in a 1:1 solution of seawater and MgCl2 (isotonic to seawater). Anaesthetized animals were gently dissected with scalpels and fixed at 4 °C over night in 4% paraformaldehyde in 0.15 M phosphate-buffered saline (PBS) with 5% sucrose, pH 7.4. Subsequently, the animals were rinsed 4–6 times for 30 min in PBS with 5% sucrose and were then stored at 4 °C in PBS with 0.05% sodium azide (Na3). 

**Immunohistochemistry**

Four specimens were stained following the protocol of Worsaae & Rouse [45]. First staining included the primary antibodies monoclonal mouse anti-acetylated α-tubulin (Sigma T6793, 1:200) & polyclonal rabbit anti-serotonin (Sigma: S5545; 1:100/1:400) or monoclonal mouse anti-acetylated α-tubulin & Anti-FMRFamide (ImmunoStar: 20091, 1:100). This was complimented by second-monoclonal mouse anti-acetylated α-tubulin & polyclonal rabbit anti-serotonin (Sigma: S5545; 1:100/1:400) or monoclonal mouse anti-acetylated α-tubulin & anti-mouse CY5 (Jackson ImmunoResearch: 115-090-099). 

Benzidine staining of haemoglobin

Using a modified version of the benzidine staining method by Knox [48], haemoglobin was stained in four fixed specimens. A 100% saturated benzidine solution was prepared by adding benzidine to distilled water. The solution was stirred for two hours. Fixed specimens were rinsed in running tap water in the same time period. Specimens were subsequently incubated in the filtered benzidine solution for 1 hour, also under stirring. Next, 5% hydrogen peroxide was added drop by drop until blood vessels turned dark blue. Specimens were either mounted in glycerol directly or dehydrated in a series of alcohol acidified with drops of 0.1% acetic acid, where after tissues were cleared in xylene and mounted in D.P.X between two cover slips. Specimens were analyzed and photographed under a light microscope (BX50 microscope, Dp71 camera; Cell software; Olympus, Japan).

**Oxygen consumption measurements**

O2 consumption was measured in seawater kept at ~100% atmospheric saturation using intermittent respirometry in accordance with Vismann and Hagerman [49]. The experimental setup was placed in a constant temperature room at 6 °C. Each experiment encompassed 3–8 measuring sequences consisting of a flushing period of 10–30 min and a measuring period of 30–45 min. The set-up had a chamber flushing rate of 30 ml min−1 and a shunt water flow of 8 ml min−1 past the O2 electrode (E5046, Radiometer Medical ApS, Bronshoj, Denmark).

The O2 electrode was connected to a blood/gas monitor (PHM73, Radiometer Medical ApS, Bronshoj, Denmark) and measuring signals were acquired continuously on a PC via data acquisition software (Labtech Notebook Pro version 12.1, Laboratory Technologies Corporation, USA). Prior to each experiment, the O2 electrode was calibrated in 0% O2 solution (saturated solution of sodium sulphite in borax) and 100% atmospheric O2 solution. The O2 consumption (MO2, µg O2 g−1 h−1) was calculated according to the equation: 

\[ MO_2 = \frac{pO_2}{100 + \frac{vw}{C_3a}} \times \beta \times v \]

where \( pO_2 = \) the O2 partial pressure at full saturation (kPa), \( vw = \) wet weight of fixed specimen rinsed for mucus tube (g) (issue fixed in 4% paraformaldehyde and stored in PBS is assumed to have similar weight as unfixed tissue), \( \alpha = \) slope of regression line for O2 decrease (% h−1), \( \beta = \) O2 solubility (µg O2 l−1 kPa−1) and \( v = \) volume of the respiration chamber (l).

O2 consumption was measured on *O. mucosparis* inhabiting three sectioned cow bone pieces (B1, B2 and B3) and bones in two cuvettes (C1 and C2). Measurements were either initiated directly...
after the annelids protracted subsequent to the disturbance of being moved (C1, C2, B1) or after one night of acclimatization (B2, B3). All measurements were corrected for background respiration. For B2 and B3 the background respiration was measured using the same water and bones (after dissection and 48 hours of acclimation to restore biological activity). For C1, C2 and B1 the background respiration was the mean value of measurements using new water, bones in two cuvettes and three sectioned bone pieces without O. mucofloris. Different respiration chambers were used for sliced bone pieces (volume: 186 ml) and cuvettes (volume: 51 ml).

**Microscale O₂ measurements**

O₂ concentration profiles were measured in vertical steps of 100 µm with Clark-type O₂ microelectrodes with a guard cathode [50] (OX-10 Unisense A/S, Aarhus, Denmark) mounted on a manually operated micromanipulator (Märzhäuser, Wetzlar, Germany) and connected to a picoammeter (PA2000, Unisense A/S, Aarhus, Denmark) and a strip chart recorder (BD25, Kipp&Zonen, Delft, Netherlands). The microelectrodes had a measuring tip diameter of 10 µm, a stirring sensitivity of <1–2% and a 90% response time of <1 second. Linear calibration of the electrode was done from electrode readings in seawater at 100% atmospheric saturation and in anoxic seawater (by addition of sodium dithionite). The O₂ concentration ([O₂], µmol O₂ 1⁻¹) at each measuring position was calculated according to the equation:

\[ [O_2] = \frac{x_n - C_{sat}}{x_0 - C_{sat}} \]

Where \( x_n = \) O₂ reading at depth n (pA), \( x_0 = \) O₂ reading at 100% atmospheric saturation (pA) and \( C_{sat} = \) O₂ concentration at 100% atmospheric O₂ saturation (µmol O₂ 1⁻¹). We measured O₂ concentration profiles from the mixed aertated seawater, across the diffusive boundary layer (DBL) and towards the surface of O. mucofloris roots in minke whale bone kept in cuvettes (WB1 and WB2) (Table 2). Prior to these measurements, manually drilled holes (diameter: ~340 µm) on the side of the plastic cuvettes (Figure 8D, E) were covered with agar (1.5% w/w in seawater) and the cuvettes were left to acclimatize for 2–3 days in order to restore the environment prior to disturbance. The O₂ concentration was measured through the holes of the cuvette wall towards the enclosed bone surface and further into the bone (Figure 8C). Measurements are given for seven sites on WB1 and five sites on WB2.

The area specific O₂ flux (J, nmol O₂ cm⁻² sec⁻¹) at the bone surface was calculated from linear parts of the O₂ concentration profiles in the DBL and agar plug according to Fick’s first law:

\[ J = D_0 \frac{dC}{dx} \]

Where \( dC/dx \) is the change in O₂ concentration (dC, nmol O₂ cm⁻²) with distance (dx, cm), \( D_0 = \) the molecular diffusion coefficient of O₂ (cm² sec⁻¹). We applied a diffusion coefficient of 1.338 × 10⁻⁵ cm² sec⁻¹, corrected for experimental temperature and salinity.

Additional microscale O₂ measurements were performed through the mucus tube wall and at the surface of the palps of the individual on WB1. On the mucus tube, the O₂ concentration was measured from outside the tube and half way into the mucus tube wall. Undisturbed measurements could not be obtained within the centre hole of the tube due to contractions of the worm. On the palps, the O₂ concentration was measured by keeping the electrode measuring-tip at a fixed position, while the palps approached the tip position as the annelid protracted after being left undisturbed.

**Acknowledgments**

We would like to thank Tom Fenchel for guidance and lending of equipment for benzidine staining and live video recordings. We also thank Per Juul Hansen for access to his Olympus BX50 microscope, Dp71 camera and CellF software. Special thanks are directed to Michael Givskov and Thomas Bjarnsholt for the many hours made available to us on their Leica TCS SP5 confocal laser scanning microscope at the Faculty of Health Science, University of Copenhagen. In addition we thank Tomas Lundøe for ship and ROV operations and Helena Wühlind for assistance at the Sven Lovén Centre for Marine Sciences – Tjärnö.
