**Introduction**

Cryptococcosis is an opportunistic systemic fungal infection and occurs worldwide, caused by several Cryptococcus (C.) species, which are saprophytic, round, basidiomycetous yeasts with C. neoformans most commonly causing disease (1, 2, 3). Infection occurs in the environment through e.g. pigeon droppings and soil rich in vegetable matter primarily via inhalation through the respiratory system. Cryptococcal basidiospores are considered the main infectious particles due to their small size of 2-3 µm, compared to vegetative, encapsulated cells (4, 5). In the desiccated state, the Cryptococcus organism may be no larger than 1 µm and may survive up to 2 years (2). In infected tissue, and often when cultured, the organism is a variable-sized yeast (3.5 to 7 µm) with a large heteropolysaccharide capsule (1 to 30 µm) (2). The majority of yeasts settle out in the nasal cavity or nasopharynx, where they can produce disease or result in animals becoming asymptomatic carriers of the organism (2).

Dissemination can occur by either direct extension or hematogenous spread (by macrophages), to the skin, lungs, eyes, or central nervous system (CNS) (2, 4, 6). Direct extension from the nasal cavity through the cribiform plate to the CNS or to the paranasal soft tissues and skin is common (2). Cell-mediated immune response results in granuloma formation (2). Direct implantation into skin wounds may also occur. Cryptococcosis is a sporadic infection, but is considered the most common systemic fungal infection in cats worldwide (3). Exposure to outdoor environments is significantly associated with the disease (7, 8, 9). While cryptococcosis in people is most often associated with immunosuppression, the organism appears to be a primary pathogen of immunocompetent cats and dogs (2). An association with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) infections in cats has been reported, and prolonged glucocorticoid treatment has been implicated as a predisposing factor in both cats and dogs (2). However, cryptococcosis is

**Summary**

Disseminated cryptococcosis was diagnosed in a cat presenting with severe dyspnoea and multiple cutaneous nodules based on cytology, serology and culture. A 3.5 years old male, castrated, domestic shorthaired cat presented with an acute history of progressive dyspnoea, tachypnoea and anorexia and a history of chronic continuous stridor, stertor and recurrent cutaneous masses.

Nasal and thoracic radiographs showed an increased opacity in the nasal cavity, a diffuse pulmonary infiltrate and a suspected cranial mediastinal mass. Thoracic ultrasound confirmed the presence of several cranial mediastinal masses. Fine needle aspiration of the cutaneous and mediastinal masses revealed the presence of encapsulated yeast cells. Culture confirmed infection with *Cryptococcus neoformans*. Latex Cryptococcus agglutination antigen test was highly positive with a titer of >1:8192. The cat was treated with fluconazole for 15 months until the titer was below detectable levels.
not more common in cats with retroviral infections (7, 8, 10, 11). Diagnostic options of cryptococcosis include cytologic examination, capsular antigen detection, and culture. Cytological finding in aspirates of encapsulated yeast cells is suggestive. Capsular antigen can be demonstrated by Latex Cryptococcus Agglutination Test (LCAAT) (12). Aetiological diagnosis is obtained by culture and mycological characterisation of the isolate.

Case History
A 3.5 years old male castrated, domestic shorthaired cat presented to the University Hospital for Companion Animals at the University of Copenhagen with a 5-days history of progressing dyspnoea, tachypnea and anorexia. The cat was born and raised in California, USA and was imported to Denmark one year previously. It had a history of long-standing respiratory symptoms, described as continuous stridor and stertor and occasionally dyspnoea, and recurrent cutaneous masses, some of which had been surgically removed. There was no history of nasal discharge and cough was only occasionally observed. The cat had been kept indoors for the past year, but had been an outdoor cat prior to that. It was current on vaccinations, but it had not been wormed for the last year. It had been treated with amoxicillin/clavulanic acid (12.5 mg/kg q12h per os) without response for the previous three days.

Physical examination confirmed tachypnoea (respiratory rate 50 breaths/minute) with an increased inspiratory and expiratory effort. Auscultation of the lungs was difficult due to pronounced stridor and stertor. Mucous membranes were pale pink with a capillary refill time of two seconds. The cat had multiple cutaneous, indolent, mobile, firm masses of varying size with a raised, smooth surface, dispersed over the whole body.

The initial therapeutic approach was aimed at addressing the respiratory distress with oxygen supplementation. After the initial stabilization, blood was collected for complete blood count (CBC), serum biochemistry, acid-base chemistry (venous blood sample) and Idexx SNAP® FIV/FeLV Combo Test. CBC and biochemistry did not show any abnormalities except for a mild stress-induced hyperglycemia. Acid-base chemistry did not show any abnormalities either, but as venous blood was used, blood oxygenation could not be assessed. Lactate was in the reference range. FIV and FELV tests were negative.

Nasal and thoracic radiographs showed an increased opacity in the nasal cavity and a diffuse pulmonary infiltrate with a broncho-interstitial pattern is visible. Mucous membranes were pale pink with a capillary refill time of two seconds. The cat had multiple cutaneous, indolent, mobile, firm masses of varying size with a raised, smooth surface, dispersed over the whole body.

The initial therapeutic approach was aimed at addressing the respiratory distress with oxygen supplementation. After the initial stabilization, blood was collected for complete blood count (CBC), serum biochemistry, acid-base chemistry (venous blood sample) and Idexx SNAP® FIV/FeLV Combo Test. CBC and biochemistry did not show any abnormalities except for a mild stress-induced hyperglycemia. Acid-base chemistry did not show any abnormalities either, but as venous blood was used, blood oxygenation could not be assessed. Lactate was in the reference range. FIV and FELV tests were negative.

Nasal and thoracic radiographs showed an increased opacity in the nasal cavity and a diffuse pulmonary infiltrate with a broncho-interstitial pattern and a suspected cranial mediastinal mass (Figure 1). Thoracic ultrasound confirmed the presence of several cranial mediastinal masses (Figure 2). Fine needle aspirates (FNA) of all cutaneous masses were performed and revealed a yellowish gelatinous content. On cytology encapsulated yeast cells were observed (Figure 3).

On day 2, fine needle aspirates of the cranial mediastinal masses and a computed tomography (CT) of the nasal cavity and thorax were performed under general anaesthesia. Recovery from anaesthesia was uneventful. In fine needle aspirates of the mediastinal masses encapsulated yeast cells identical to those from the cutaneous masses were demonstrated (Figure 3). Computed tomography revealed soft tissue masses in the nasal cavity and frontal sinus, nasal turbinate destruction and deviation of the nasal septum, soft tissue nodules distributed throughout the lungs and lung consolidation in the ventral lung field (Figure 4). Aspirated material from a cutaneous nodule was cultured on Sabouraud dextrose agar (CM0041, Oxoid, Basingstoke, Hampshire, England). After incubation at 30° for 7 days, growth was observed of grey-white, mucoid colonies consisting of budding yeast cells with capsule formation (Figure 5). A subculture was identified as Cryptococcus neoformans by using the API 20C AUX kit (BioMerieux,
The severe findings on radiography and CT indicated irreversible chronic intranasal changes and marked pulmonary pathology with intrathoracic granulomata which might prevent full recovery, so that ongoing respiratory sounds and decreased lung capacity would be expected. The presence of CNS disease caused by cryptococcosis is the major factor described to influence outcome in cats (13). In our case, the cat did not show any signs of CNS involvement, but as imaging studies of those regions were not performed, this could not be definitely ruled out. Our patient had a LCAAT titer >1:8192 which correlated positively with the disseminated distribution of the disease, as patients with disseminated skin and/or lymph node involvement have significantly higher titers (12). Although the prognosis of cryptococcosis should be considered as guarded, a majority of cats can be expected to be cured, but treatment is protracted and expensive (13). We initiated treatment with fluconazole, an azole antifungal, which is described to be very effective in the treatment of feline cryptococcosis, including cases with advanced, longstanding, or disseminated disease (2, 13, 14). Furthermore, this drug can be given orally. Side effects in cats can be inappetence and, rarely, increased liver enzyme activity and hepatic toxicity (14). On follow-up visits, liver enzyme activity and LCAAT titers were measured to monitor progress, evaluate prognosis, and guide cessation of treatment (2, 12, 15, 16). The cat responded well to treatment and no side effects were observed. Antifungal therapy was continued until the LCAAT titer declined to an undetectable level after 15 months of continued therapy. This was a significantly longer treatment period than described in a previous study where the median duration of treatment with fluconazole in cats
with less severe cryptococcosis was 4 months with a range of 1 to 8 months (13). Due to the advanced disease progression in our patient, a longer treatment period was expected. Despite clinical improvement, resolution of the cutaneous masses and a finally undetectable LCAAT titer, a full recovery with resolution of all respiratory symptoms seems unlikely due to the severe intranasal anatomical changes.

This case report emphasises that it is important to consider cryptococcosis in cats with respiratory symptoms with or without cutaneous involvement due to its worldwide significance, particularly in cats from countries with a high prevalence of cryptococcosis.
